THE NEW *Mail and Express* BUILDING, in which the offices of THE ELECTRICAL ENGINEER are situated, when fully completed will be one of the best electrically equipped buildings in the country. The Waddell-Entz Electric Co., of this city, have just been awarded the contract for installing four 75 h. p. direct-connected dynamos of their multipolar type which will serve as the generating plant for furnishing current for lighting and motor work. In addition to the generators they will install no less than 20 motors of all sizes from 40 h. p. down. These will be employed to drive the *Mail and Express* printing presses, and stereotyping machinery, for ventilation and other purposes.

"KERITE" IN NEW QUARTERS.

TIME-HONORED, by being about as old as the electrical business itself is, and having by its many virtues given to not a few electrical inventions their first hopes of success, "Kerite" still pursues its way and there is no reason why fifty years hence some journalist of the time to come will not be singing its praise in the confidence that he can put it more than "pretty strong" without fear of contradiction. While we may not assist at the centennial of this famous insulation, which like the stream immortalized by Tennyson sees a good many human entrances and exits in the electrical field, we shall be only too glad to attain a hale and hearty old age such as it may claim, and like it, be as good as ever after years of strenuous test and trial. During the last few years "Kerite" has done more than hold its own, and has pushed for new fields, keeping pace with the advance of the business; and even when other wires have been used its proprietors have been magnanimous enough to sell "Kerite" tape to patch up leaky places in them. Owing to the growth of the business, the management have lately been enlarging their facilities, and they have now also taken new offices, by moving into the fine new *Mail and Express* Building, 166 Fulton street and 203 Broadway, where they have secured very handsome and commodious quarters on the third floor, overlooking the turf and tulips of St. Paul's churchyard. Another important change that has been made is that by which Mr. W. R. Brixey, who has so long managed the factory with notable success, will also bring his energy and push to bear on the general direction of affairs for Mrs. Day at the New York headquarters. Mr. Brixey will divide his time between Seymour and New York, and is already buckling down with great vim to these double duties. "Kerite" is more than ever to the fore and hangs its banner on the outer wall and its wire on the inner of many of the modern buildings going up all over the country, besides being used more freely year by year in the older telegraph and telephone industries.

THREE DAYS AT NIAGARA FALLS.

THE West Shore Railroad is to run a special excursion Saturday, May 28, 1892, to Niagara Falls, and Buffalo. Tickets will be good going only on special train leaving West Shore station on above date and good for return passage on any regular train on or before May 31, 1892. This trip is of special interest to electrical people just now in view of the work going on in the great hydraulic tunnel.

WHY NOT TAX THE CURRENT AS WELL?

WE are confident that a recent importation of dutiable merchandise at Jupiter, Fla., has not escaped the vigilant eye of Assistant Secretary Spaulding, who writes the decisions in which the Treasury Department interprets and applies the provisions of the McKinley tariff. We refer to the landing at Jupiter of the American end of the new telegraph cable from Nassau. The law with respect to imported goods of this kind has already been interpreted and applied by Mr. Spaulding. As soon as the American end of the telephone cable from the Canadian town of Windsor emerged from the water at Detroit a few months ago, the watchful Assistant Secretary promulgated a decision that it was clearly dutiable and must be taxed under the law of McKinley. The decision has been published by the department, and so far as we know has never been reversed. The American end of the Nassau cable was landed at Jupiter on Saturday last, and the British steamer *Westmeath*, after doing the work, slipped away in the darkness of the following night. The protruding end of this cable should be appraised at once, and the full duty should be exacted.—*New York Times*.

THE FORD-WASHBURN STORELECTRO COMPANY.

ELECTRICIANS are showing great interest at the present time in the new storage battery just being placed on the market by the Ford-Washburn Storelectro Company, of Cleveland, Ohio. A representative of THE ELECTRICAL ENGINEER had the privilege, some days ago, of witnessing a number of tests to which one of these cells is habitually subjected. Perhaps the most interesting of these performances was the repeated short-circuiting of a cell without the least perceptible effect on it. Large heavy copper strips were run from a cell through an ammeter of practically no resistance and the whole charge of the cell discharged through it.

The ammeter showed between 350 and 400 amperes, keeping it right up until just before the cell was exhausted, when it slowly dropped to zero. The same process may be repeated as often as desired. The battery has no grids, cannot buckle, and according to the opinion of leading patent experts in this country is not an infringement upon the Brush patent. The company has been running a car fitted with its new battery for some months over the Woodland and West Side lines, also over the Euclid avenue and Central avenue lines with great success. The officers of the company are as follows: George A. Ford, president; J. F. Parkhurst, vice-president; W. H. Marshall, treasurer; Edward S. Ford, secretary. The company besides preparing to push its battery aggressively, will also continue the manufacture of dynamos, motors, etc. There seems to be no reason why the storage battery may not be guaranteed electrically for three years at least, and it only remains to see what mechanical modifications, if any, shall be indicated as the battery is adopted for different kinds of work.

HUYETT & SMITH MANUFACTURING CO.

THE HUYETT & SMITH MANUFACTURING CO., of Detroit, Mich., which has just brought out a combined exhaust fan and motor, in which the armature and fan are on the same shaft, is preparing for a lively summer. The company is now having great difficulty in keeping up with its orders for all sorts of exhaust fans, and owing to its compactness and great efficiency, the new combination fan bids fair to enjoy a brisk scale.

The Huyett & Smith Co. also are very successful with their system of heating, which has already been adopted by a number of electric light and power companies. The heat of exhaust steam is used and distributed by means of fans and large pipes; in summer the same plant can be used as a cooling device, the air being passed over coils of pipe through which ice water is running. The company frequently puts in a plant with a guarantee to keep the temperature of a building, say, at 70 degrees the year round, regardless of the conditions out of doors. As the new type of combined motor and fan can be used in summer, any building, such as a church or theatre, may be kept cool by simply taking current from the nearest mains, thereby avoiding the necessity of keeping up fires and steam. Theatre managers, especially our enterprising New York managers with summer attractions on their boards, would do well to look into this matter.

SOUTHERN NOTES.

THE CITY HILL, RICHMOND, VA.—We extract the following notice from the Baltimore *American*, of April 22d, regarding the conduit system of the Interior Conduit and Insulation Company, of New York: "The contract for the electric equipment and interior wiring of the new City Hall, at Richmond, Va, was awarded yesterday to the Southern Electric Company of this city. This is one of the largest contracts of the kind ever made. The company will use the Interior Conduit Company's system throughout, which comprises a method of insulating tubing, together with all the modern appliances for safety and convenience, giving full control of the electric plant at one central point in the building. The contract was awarded to the Baltimore house owing to the superiority of their work, although they were not the lowest bidders."

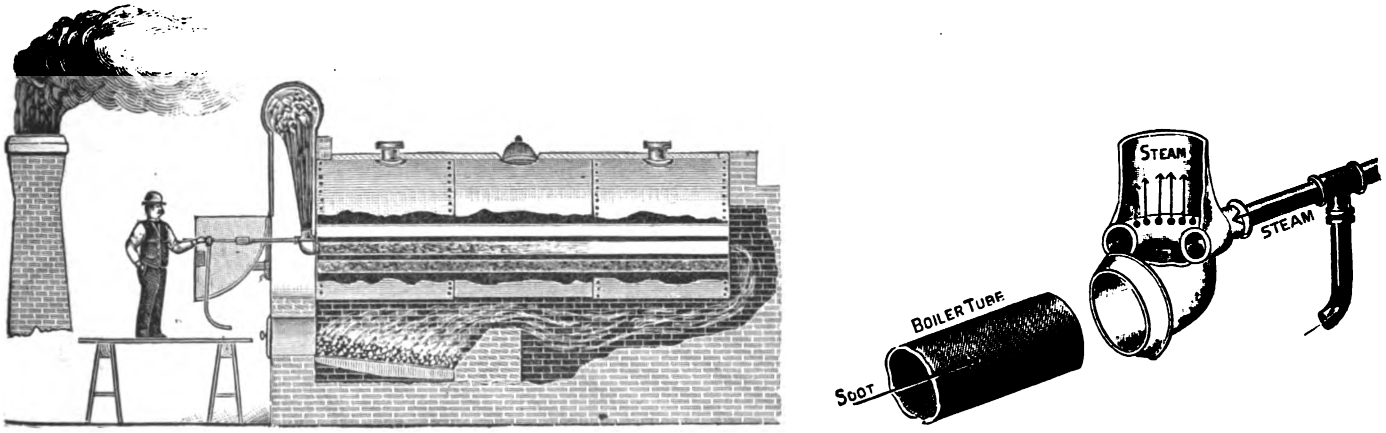
THE RIES ELECTRIC SPECIALTY COMPANY, of Baltimore, are meeting with remarkable success in the sale of their Ries regulating socket.

LOCKPORT GAS LIGHT CO., Lockport, N. Y., have added another 100 h. p. Ball engine, manufactured by the Ball Engine Co., Erie, Pa., to their present very complete electric light plant.

MESSRS. F. R. DRAVO & CO., Pittsburgh, representatives of the Ball Engine Co., Erie, Pa.. have made installations of Ball engines in the following office buildings in Pittsburgh: The Central District Telephone and Telegraph Building, the Vandergrift Building, and the Schmidt Building.

BALDWIN'S VACUUM BOILER TUBE CLEANER.

As long as the steam boiler continues to be the initial source of energy for electric light and power plants, any device for improving the condition of boilers, or preserving them in good working order, will be of interest to the electrical engineer. One of the greatest inconveniences in the use of boilers for any purpose is the perpetual tendency of the tubes to become filled with soot, which not only soon fills the entire tubes but gathers in large quantities at the back of the fire bridge wall and at the back end of the boiler. The heating surface of a boiler in this dirty condition is seriously impaired, and many devices are in use, more or less effective, for cleaning out the tubes and the chambers. We take occasion this week to show our readers the latest device in this line, Baldwin's vacuum boiler-tube cleaner, which possesses many entirely new and important features, and utilizes the vacuum principle, an entirely new adaptation in boiler-tube cleaners. Fig. 1 shows a section of a boiler, illustrating the method of applying the cleaner, with the soot and dust being *drawn out* of the tubes and forcibly *ejected up* the chimney. Fig. 2 shows the cleaner in section, from which the principle of its action will be readily understood. The heater is made of a brass composition, and is shaped like an elbow. It has a conical-shaped mouth for insertion in the tube. The steam is admitted into the back of the cleaner and passes into an annular chamber, surrounding the passage for the gases and soot, with small perforations on the upper side. When the steam is turned on it rushes upwards through these holes, and creates a vacuum, thereby drawing out all the accumulation of soot in the tube, *in the direction of the natural draft*, and sending it where it ought originally to have gone, that is, up the chimney. By this method no steam is admitted into the tube, and therefore *no scale* is formed, and the inside of the tubes is always kept dry. The steam being wire-drawn through the small apertures, is first superheated, and becomes thoroughly dry, so that it is impossible for the soot to stick in the chimney or passages. One of the greatest advantages of this method, is the fact that as the soot is drawn out in the direction of the draft, and not blown around the boiler-room or into the other tubes. This prevents in a large measure the disagreeable work of cleaning out the back connection. It is the opinion of many who have used this cleaner, that it is the best ever invented, as it works on the right principle, and is most practical and clean. It keeps the stack and combustion chamber clean, and will actually even draw out all the soot and dirt which accumulates back of the fire bridge wall. The Baldwin cleaner is manufactured by the Oliver P. Clay Company, of Cleveland, Ohio, and is the invention of Mr. F. Ruel Baldwin, M. E., of New York, who is also agent for New York State. Messrs. S. C. Nightingale and Childs, of Boston, are the agents for New England and are already introducing it into a large number of boiler-rooms in the East.



Figs. 1 and 2.—Baldwin's Vacuum Boiler Tube Cleaner.

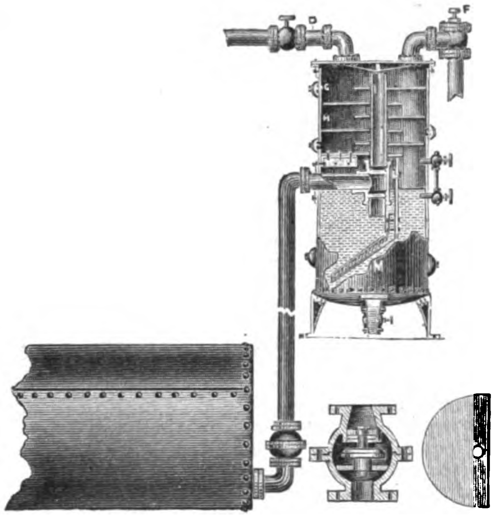
THE RAILWAY EQUIPMENT CO.

Mr. W. R. Mason has purchased in behalf of the above company, of which he is general manager, the capital stock, entire business, stock in trade, etc., of the Electric Merchandise Co. The consolidated business will be carried on under the name of the Railway Equipment Co., which has its headquarters in the Pullman Building, Chicago, where it will continue to build up its trade as only a first-class mason can.

The 150 h. p. engine furnished the Kittanning Electric Light, Heat & Power Co., Kittanning, Pa., was started some time ago by F. R. Dravo & Co., Pittsburgh, agents of the Ball Engine Co., Erie, Pa. The engine gives universal satisfaction.

THE BUFFALO FEED-WATER HEATER AND PURIFIER.

Every one connected with the management of steam boilers is familiar with the care and labor required to keep them clean and prevent the formation of scale or incrustation on the heating surfaces, and many devices for obviating this difficulty have been invented. One of these, the result of much careful study and experiment, is shown in the accompanying illustration. The inventor Mr. Robert Learmonth, of 200 Bouck avenue, Buffalo, N. Y., has become convinced that the method of precipitation is the most efficacious for the purpose and has devised his apparatus accordingly.



Buffalo Feed-Water Heater and Purifier.

The water, entering the purifier at the top, is heated by direct contact with the steam and falls from one to another of the spray plates to the settling chamber at the bottom, whence, after passing under the division plate, and up through the centre tube, it enters the boiler. Not only are all substances having a higher specific gravity than water prevented from passing into the boiler, but those substances having a lower specific gravity are also excluded by the equalizing tube in the centre, extending below the surface of the water and preventing all floating substances from entering the tube.

Unequal expansion is also prevented, as the water is heated to the required temperature before entering the boiler.

The purifier is simple, durable and effective. There are now twenty of them in use on steamers on the lakes, and twenty-five on stationary boilers on land, all of which have given entire satisfaction.

A SCIENTIFIC INVENTOR.

The *Industrial World* of Chicago remarks: "It is sometimes said that scientific men have never invented anything, but this is not true of Dr. Otto, who is known all over the civilized world as the inventor of the first economically and commercially successful gas engine."

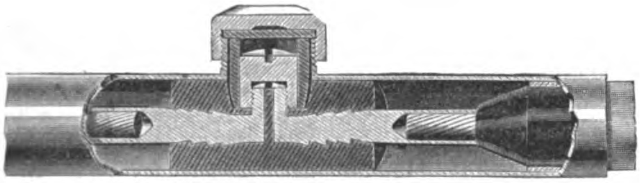
THE RAILWAY EQUIPMENT CO.

THE RAILWAY EQUIPMENT COMPANY having temporary offices at 617-619 Pullman Building, Chicago, is beginning business in a noticeably energetic manner. Already many large contracts have been filled from an improvised stock, while the number and importance of orders being received daily, show the confidence the trade has in the reliability of the new company. With the aggressiveness characteristic of the officers of the company, who are well known in the electrical business, having occupied similar positions with a former company, the new concern has purchased the Electric Merchandise Co. This will put it in position at once to fill all orders immediately, and do away with the difficulty of creating a new and complete stock. The many standard devices which hitherto have been handled by the Electric Merchandise Co. will be furnished by the new house, along with a number of new fixtures, which long experience in electric railway construction has developed. These facts place the Railway Equipment Co. in the first rank of electrical concerns at once, without the anxiety due to experiment making. Having purchased the only company with exclusive business in manufacturing and furnishing electric railway supplies, it now assumes the same position. It will give its whole attention to supplying the needs of electric railways of whatever system. That will be its exclusive business. It will advocate no particular system and believes in all alike. Mr. W. R. Mason's connection with the Railway Equipment Co. as general manager, will do much to recommend it to all railway companies, old and new.

CUTTER'S NEW CONDUIT CONNECTOR.

THE need of some means of disconnecting underground arc circuits in order to test them, has shown itself in the demand for the conduit connector put on the market a year ago by George Cutter, of Chicago. Since then, the experience with it has suggested a number of modifications which make the latest form both simplier and more serviceable.

The illustration shows this new pattern, which has metal terminals moulded in a block of hard rubber, connection being made or broken through a metal screw cap. The ends of the two cables are soldered into the split terminals, and the brass shell which is made to fit the lead covering on the cable is readily brazed into a solid mass with the lead. A suitable rubber insulation keeps the outer cap out of circuit and makes it air-tight. This form of connector is quickly put in place and allows the ends of the two sections to be disconnected in a very few minutes. George Cutter has made many hundreds of them for use in Chicago alone, where a year's experience has shown this conduit connector to be indispensable for the safety of the circuits.



CUTTER'S NEW CONDUIT CONNECTOR.

THE EDISON TELEPHONE AND TELEGRAPH CABLES.

As electrical knowledge becomes more widespread, and the manufacture of electrical apparatus rises towards perfection, customers become increasingly fastidious. Fully posted as to the new developments, and provided with the latest measuring devices, their demands call forth new efforts on the part of the manufacturers. This has been especially true of wires and cables. Considerable difficulty, for example, has been experienced in lowering the static capacity to the figure stipulated in the specifications of the telephone and other companies. A short time ago a figure of .20 or .21 microfarads was considered satisfactory, but this has been decreased year by year until now .080 microfarads is required.

Although the Edison General Electric Co. have for many years past been manufacturing telephone cable, they have only recently put in the immense lead presses which now enable them to turn out complete lead-covered cable. With these new facilities, their difficulties in the direction just mentioned have been overcome, and several cables lately shipped have shown a static capacity of not more than .075 microfarads. In striving to lower the static capacity, the matter of insulation has not been neglected, and a remarkably high insulation has been obtained in the case of every cable which has left their works.

The one feature, however, in which they may be considered to excel, is their lead cover. It has been customary, and indeed is still the general practice, to press the lead over the core in a semi-viscous state, the molten lead being poured into the press. Lead in this condition carries on its surface a thick scum consisting of various impurities, oxides, etc. This can be partially removed by a ladle, but it is impossible to remove it entirely, and even when pouring the lead into the press, considerable oxidation necessarily takes place, as lead oxidizes immediately on contact with the air, especially when in a molten condition.

Recognizing that such a cover could not be homogeneous and would be far more subject to attack by gases and acids than a pipe consisting of pure lead, the Edison Company determined to adopt the process of Siemens & Halske and their presses, and use absolutely cold lead. From the slugs of lead every particle of oxide is removed before insertion in the press, and as the pressure is increased the lead is pressed out over the cable, enclosing it in an armor impervious to air or water. Comparison between cables armored by the cold-press process and those covered by the hot-lead process has proved the superiority of the former. It is an undisputed fact that if two pipes filled with water be taken, one made by the hot process and the other by means of the cold press, and subjected to high atmospheric pressure, the fluid will ooze through the former while the outside of the latter will remain perfectly dry. This has been very prettily shown by coloring the water in the pipes with aniline, which could be plainly seen on the outside of the hot-pressed pipe after subjection to great pressure.

Cable recently supplied to the Metropolitan Telephone Company, of New York, has received unqualified approval, and although dry core was used, the cable could be handled as well as one made with the saturated core. The uniform gauge of the cable and its smoothness were also matters of appreciative comment. The Pacific Telephone & Telegraph Company, of San Francisco, recently placed a large order for this cable, the lead sheathing enclosing no less than 100 pairs of wires.

RAILWAY WORK IN DUBUQUE, IOWA.

MR. J. A. RHOMBERG has concluded arrangements for the remodeling of his electric street railway in Dubuque, Iowa. The Detroit Electrical Works furnish the equipments for 30 Standard motors, while the J. G. Brill Company are building six new motor cars, and the St. Louis Car Company have obtained the contract for ten trailers.

The overhead work comprising the setting of poles and wiring was let to the Edison Company, who will also furnish a generator. Some smaller contracts were made, the whole amounting to about $75,000.

Mr. Rhomberg intimates that from the many systems, he has selected the very best and proposes to have one of the best equipped lines in the country.

THE DONALDSON-MACRAE STORAGE BATTERY IN PHONOGRAPH WORK.

IN a recent issue one statement made it appear that a Donaldson-Macrae storage cell had run a phonograph for 100 consecutive hours. This should have read 160 hours, as attested by the following letter received by the company:

THE COLUMBIA PHONOGRAPH COMPANY.
BALTIMORE, September 4, 1891.

W. W. DONALDSON,
President. Donaldson-Macrae Electric Company, Baltimore, Md.

Dear Sir.—The Donaldson-Macrae electric storage battery delivered to us August 28, 1891, composed of seven plates, the weight of the elements being thirty three pounds, the total weight being fifty pounds, we started on the above date on a motor phonograph, in our office, and ran for one hundred and sixty (160) *consecutive* hours. This is the best record of any battery of the same weight which we have used.

From the few number of plates and the general construction of the battery and the capacity thereof, we do not hesitate to say that in our opinion this is the best storage battery which has yet been produced for phonograph work.

We beg to remain,
Yours truly,
(Signed) COLUMBIA PHONOGRAPH CO.,
Baltimore, Md.,
By N. R. BARNES, Manager.

ELECTRICAL ACTIVITY AT PEORIA, ILL.

THE First Baptist Church was formally dedicated last Sunday. It is furnished throughout with incandescent lamps, 175 being used in all. They are run on a 50 volt alternating circuit. Current is furnished by the Jenney Electric Light and Power Co.

H. R. WOODWARD, general manager of the Central Railroad Company, has resigned, and J. H. Findley will be his successor.

THE city council has granted a franchise for another electric railroad to operate in the territory between the two existing lines. It will probably be run in connection with the Central Railroad.

THE power house for the Ft. Clark electric line is finished, and the machinery is being put in position. The track and wire work are also nearing completion. They expect to be running by May 10.

THE CENTRAL RAILROAD COMPANY are laying a new track on the Main street hill, and are using 65 pound rails.

THE FORT CLARK RAILROAD have filed for record a mortgage on the road for the sum of $250,000. It was given to the Illinois Trust and Savings Bank of Chicago. This represents the electric equipment of the street car company in question.

OPENING OF THE YONKERS, N. Y., ELECTRIC RAILWAY.

The Yonkers Electric Railroad was opened for general traffic on Monday, May 2, and cars are now running regularly, giving general satisfaction by their smooth and noiseless riding. The outfit of the generating station is of the most improved type, containing two Edison 100-kilowatt dynamos, directly belted to high speed Ball & Wood engines. Gearless motors of the Eickemeyer-Field system are used, which drive both car axles by means of parallel rods from one 20 h. p. slow speed motor, thus avoiding all noise and wear and tear incident to high speed machinery.

This road is of special interest owing to the fact that the rails have not been relaid, but the old horse car rails, which had done service for many years, have been left undisturbed, and have only been bonded. This course has been pursued because in this type of gearless motor the whole motor weight rests upon the car springs, and hence the destructive blow exerted upon the rails by the momentum of the motor is entirely eliminated.

THE VARLEY ELECTRIC TIME CALL.

This call is designed as a labor-saving apparatus, and to make absolute calls and service in hotels, livery stables, and other places in which it is desired to give prompt attention and security to customers, and is of use also in hospitals, factories, offices, and in fact in any place where punctuality is necessary.

It is a common thing for a business man to put up at a hotel, for the express purpose of getting away on some important business engagement, instead of staying at home over night, leaving in the office of the hotel a "call" for the morning. The clerk enters the time in his book and the guest retires, believing he will be called in the morning at the proper hour; sometimes he is, but frequently he is not. With the time call, illustrated herewith, the forgetting of the time is almost impossible.

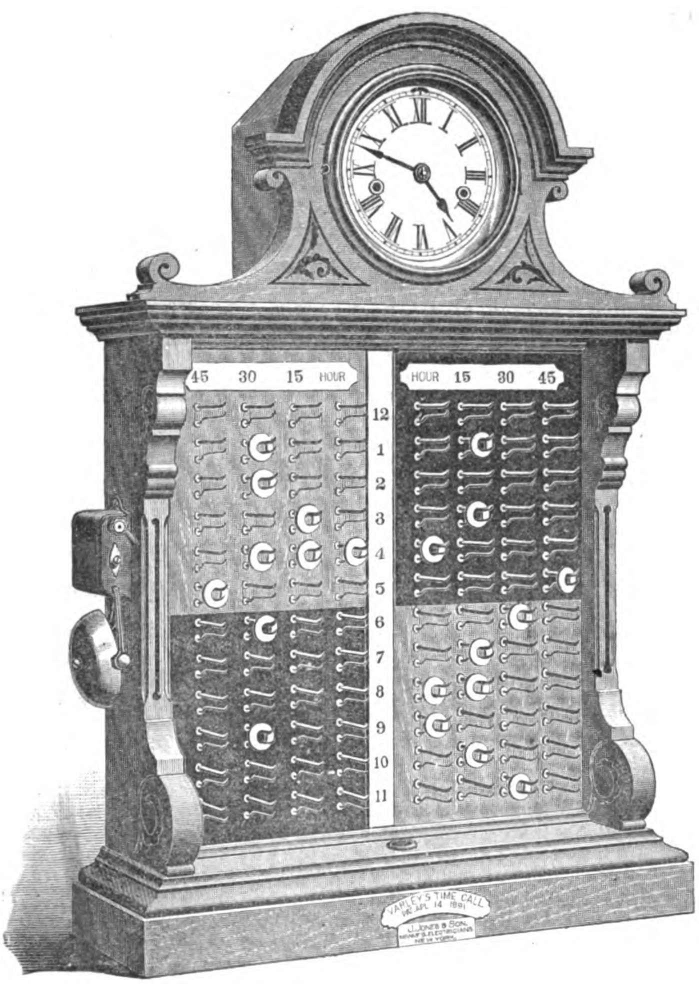


Fig. 1.—Varley Electric Time Call.

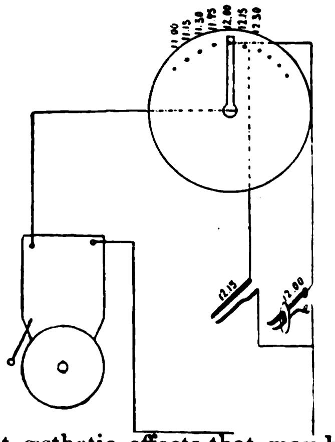
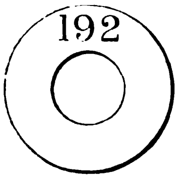
The general appearance of the call is shown in Fig. 1, while Fig. 2 shows the connections. Beneath the clock are the pins arranged in line with the hour, quarter, half and three-quarter hour lines. When a guest desires to be called at 5.45 a. m., the clerk takes a tag, Fig. 3, which is of metal, numbered in accordance with his room, from the keyboard, slips it over the two metal pins under the figure "45" and to the right of the figure "5," these two forming the hour for call. The placing of the tag in this way closes the circuit at that point, and only needs contact on the clock dial to complete the entire circuit. Nothing further is required until the clock reaches the time of 5.45, when the bell will ring, and





highest æsthetic effects that may be reached with correct taste and judgment.

II.

The house taken as the best illustration in New York of the furthest advance in modern electrical engineering practice as applied to residences is that of Edward H. Johnson, Esq., 36 West Fifty-sixth street. Like many others in the

continue to ring until the tag is removed. This tells at once the room to be called, and there is no possibility of mistake if there is any one about to hear the bell.

When ten guests are to be called at the same time, ten little room tags are placed on pins in the same manner as one. The dark portions of the board represent night, and the light portions day.

Other tags are manufactured with a metal interior ring capable of closing the circuit, while the rest of it is made of a composition on which memoranda may be made. This enables the clerk to tell whether room 192, for instance, wants cigars, ice-water, etc.

For convenience of having tags at same point at which the instrument is placed when so desired, a board is furnished with hooks numbered to correspond with the number of rooms.

The time call is handled by Messrs. J. Jones & Sons, 602 West 22d street, New York.

THE PURITY OIL FILTER.

The Purity Oil Filter Manufacturing Co., of 107 First avenue, Pittsburgh, have an excellent oil filter, the use of which would save a large proportion of the oil expense in central stations and power houses. It has already been tried in a great many places with unvarying success, and recommends itself by cheapness, simplicity and efficiency. Among the latest sales are those to the following concerns: New Castle, Pa., Wire Nail Co.; Pittsburgh Wire Co., Braddoock, Pa.; Pacific Rolling Mill Co., San Francisco, Cal.; California Elec. Co., San Francisco, Cal.; Golden Reward Mining Co., Deadwood, So. Dak.; Robt. H. Thorborn, Rapid City, So. Dak.; Pittsburgh Traction Co., Pittsburgh, Pa.; Henry Likly and Co., Rochester, N. Y.; Thomson-Houston Electric Co. for the Little Falls, N. Y., Electric Light Co.; Central District Telephone Co., Pittsburgh, Vandegrift Building, Pittsburgh, Pa.

ELECTRIC LAUNCH AT THE CRYSTAL PALACE EXHIBITION.

Messrs. Woodhouse & Rawson have lately added to their stand, at the Crystal Palace, an electric launch, and we doubt not the following particulars concerning the same will be of interest to our readers: The "Lily," as she is named, is 28 feet long, and has a beam of 5 feet 6 inches, a depth of 2 feet 10 inches, and a draft of two feet. The sides of the boat are carvel built of mahogany, with American elm keel and timbers, and she has an oak stem, stern post and dead-wood.

The electrical equipment consists of a 2 h. p "W. & R." motor, with current from 30 "Epstein" cells. Her weight, complete, is supplied 25 cwt. She will hold from 12 to 15 passengers, and with one charging, which occupies about four hours, will run at full speed (seven miles an hour) for five hours.

NEW YORK NOTES.

Messrs. P. Claus & Co. have opened offices at 52 Broad street, New York. They have made arrangements with a well-known company for the manufacture of their dynamos and motors, and in addition will do inspection and expert work, etc. They have sold a 3,300 incandescent light machine for use in Hammerstein's new Manhattan Opera House on 34th street, New York, and one of their 400-light machines will be installed in West 125th street in a new club and restuarant, while two 600-light dynamos go to Boston. A 1,000-ampere, 10-volt machine for electro-deposition goes to Philadelphia. The generator manufactured by Messrs. Claus & Co. is of the well known "Continental" type, and they are now prepared to undertake the installation of dynamos and motors for all classes of work.

Mr. Thomas S. Crane, patent expert and solicitor, formerly of Newark, N. J., has removed to New York, and is now established in room 282 Stewart Building, Broadway and Chambers street. Mr. Crane has followed his profession, with offices in Newark, for thirty-five years, where he has conducted a practice reaching over a wide territory and a large variety of inventions. Having for some years found it necessary to spend most of his time in New York, Mr. Crane has determined to make this city his headquarters henceforth. He has had a large and successful experience in electrical cases and in cases involving general physics, and will doubtless be generally welcomed to New York as an important addition to the ranks of patent solicitors and experts.

CUTTER'S NEW CONDUIT CONNECTOR.

The need of some means of disconnecting underground arc circuits in order to test them, has shown itself in the demand for the conduit connector put on the market a year ago by George Cutter, of Chicago. Since then, the experience with it has suggested a number of modifications which make the latest form both simplier and more serviceable.

The illustration shows this new pattern, which has metal

Berrang & Zacharias, the electrical contractors of 712 Cookman avenue, Asbury Park, N. J., are a most pushing and enterprising concern, and they have been doing a large amount of work in their vicinity. They carry a large supply of novelties and standard goods in their store. They have lately issued a very clever and pithy pamphlet, in which in the form of a conversation they advance a number of excellent arguments in favor of the various uses of electricity for light and power.

Mr Edward A. Maher, formerly mayor of Albany, and for some time the manager of the Albany Electric Illuminating Co., is coming to New York to take the presidency of the large "Huckleberry" system of trolley roads in the annexed district of New York city. It may not be generally known that Mr. Maher has once or twice been a favorite for the presidency of the National Electric Light Association.

The Sprague Electric Elevator Co. of 15 Wall street, have closed a contract with the Grand Hotel for one of their high speed passenger electric elevators, to take current from the local lighting mains. The company has been fortunate in securing the services as general agent of Mr. Charles A. Benton, late manager of the railway department of the Detroit Electrical Works. He is a host in himself.

W. R. Fleming & Co. have issued notice of their removal to the new Mail and Express Building, 203 Broadway, where they will enjoy larger quarters. They have been awarded the contract for four of their Ideal self-oiling automatic engines for the building and will thus be able to exhibit to their visitors, right on the premises, one of the finest examples of engine practice in the country.

The D. F. Frisbie Company, New York and New Haven, have secured desirable offices in the Mail and Express Building and are well nigh settled in their new quarters, where they will continue to handle their well-known specialties, including their combination of an elevator with C. & C. motor.

The U. S. Horse and Cattle Show Society has been giving a fine show during the week at the Manhattan Field, and the sports during the evening sessions were brilliantly lighted by the Mount Morris Electric Light Company under the direction of Superintendent C. G. Young.

The Fort Wayne Electric Company has removed from 115 Broadway to offices in the Edison Building, 42 and 44 Broad street, where, as before, they will be in charge of Mr. H. C. Adams.

Drake, Payson & Whittier, of Providence, R. I., have accepted the agency of the Security insulator for Rhode Island.

The Security Insulator Company have recently received some flattering testimonials from users of their insulators.

S. G. Booker, manager of the Fidelity Carbon Co., of St. Louis, spent several days in New York last week.

WESTERN NOTES.

The Electric Appliance Company are getting in shape for the summer trade on fan motors, and have secured the agency for the Meston alternating current fan motor, which, on account of its reputation as the first alternating fan motor on the market, is apparently going to have a very large sale the coming summer. The motor has been very much improved over last year's model. Some of its special features are regulation of speed at will, self-oiling bearings and carbon brushes which will last an entire season. No cost has been spared in the manufacture of the machine, and it is certainly a very handsome fan motor. The Electric Appliance Company are now exhibiting the first one of the 1892 pattern that has been received in Chicago, and it is exciting favorable comment from all who see it.

The M. C. Bullock Mfg. Co. have opened a hadsome new store, corner of Canal and Washington streets, Mr. A. B. Coulton, manager, where they carry a sample line of their well-known specialties, including Bullock-Corliss engines, Lane's band friction hoists, diamond-pointed core drills, wire rope haulage, rock drills and air compressors, Champion ventilators and a general line of mining machinery. They have also become the Chicago agents for the well-known Mundy hoists for contractors, quarrying, pile driving, etc.

The Electrical Supply Co. are filling their usual large orders in their three specialties, namely, "Shield" brand, Stanley transformers and Sunbeam incandescent lamp.

Mr. James G. Biddle, representing Queen & Co., Philadelphia, was a caller at the Western office of The Electrical Engineer last week.

PHILADELPHIA NOTES.

Mr. Wm. Hazelton, 3d, for a year or more in charge of the Philadelphia office of the Short Electric Railway Company, has been called to the home office in Cleveland, Ohio, to take the position of assistant general manager. Mr. Hazelton's well-known energy and business ability will, by this change, be used in a larger and more important field, and the representatives of other electrical companies who have had reason to fear him in competition with street railway men, cannot congratulate themselves that he is now out of their way, as his supervision of an important Eastern territory heretofore under his control will be as unremitting as ever. Mr. Hazelton is to be congratulated on his advance to a more important position.

Mr. J. Paul Gaylord, formerly with the Electro-Dynamic Company, was elected president and general manager of the Pennsylvania Electric Engineering Co. last week, while Mr. Lewis R. Schultz has been retained as secretary and treasurer. Mr. Gaylord has made a host of friends in Philadelphia and vicinity while with his former company, all of whom he would be pleased to meet at the quarters in the Penn Mutual Building. The Pennsylvania Company under its new management will continue as agent for the National alternating system apparatus, and will push their specialties, the Pennsylvania lamp, socket, switch and tape, besides keeping a stock of general electrical supplies on hand.

Mr. G. A. Wilbur, Philadelphia agent for the Fort Wayne Electric Co., reports the following sales since April 1st: Three 60 Wood arc light machines, Reading Light & Power Co.; one 60 Wood arc light machines, Shamokin (Pa.) Street Railway Co.; one 60 Wood arc light plant, Hamburg (Pa.) Electric Light & Power Co.; and four additional 60 Wood arc light machines and 240 lamps to the Southern Electric Light & Power Co. of this city, which gives the Southern Company a capacity of 600 arc lights of the Wood system.

The Supply Manufacturing Co., of 100 Wood street, Pittsburgh, Pa., is probably the largest company in this country make a specialty of commutators. This company has increased its plant until it now occupies the entire building of four stories at the corner of Wood street and First avenue, and is well equipped for the manufacture of railway and electric light supplies.

Pepper & Register have greatly increased their manufacturing facilities by leasing the entire building of four floors located at 117 to 121 North Front street, Camden, N. J. This firm is about to bring out some new apparatus which will be especially interesting to street railway people.

The Heisler Electric Co. will soon be out with an entirely new outfit of apparatus that will cover the general field of electric lighting and are now prepared to furnish estimates for the installation of complete storage battery plants.

THE
Electrical Engineer.

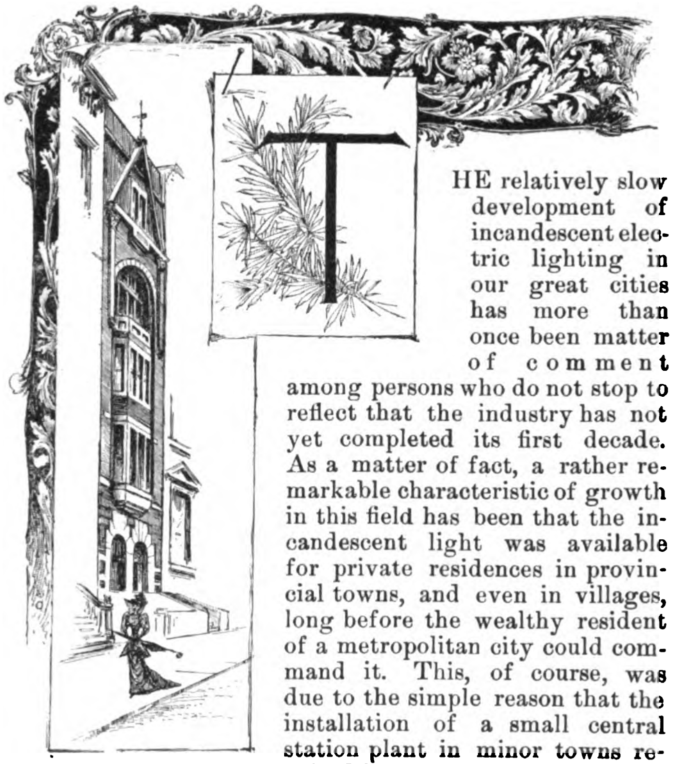
VOL. XIII. MAY 25, 1892. No. 212.

ELECTRICITY IN A MODERN NEW YORK HOUSE.

BY

T. C. Martin

I.



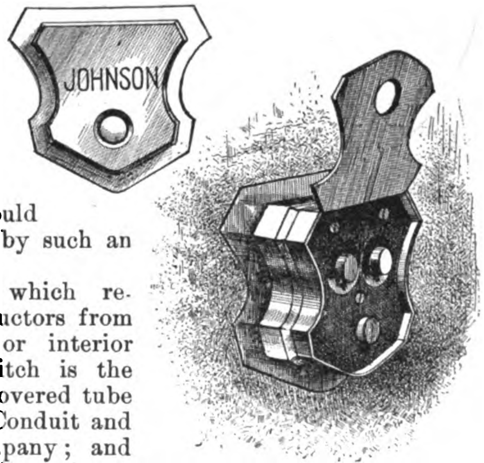
THE relatively slow development of incandescent electric lighting in our great cities has more than once been matter of comment among persons who do not stop to reflect that the industry has not yet completed its first decade. As a matter of fact, a rather remarkable characteristic of growth in this field has been that the incandescent light was available for private residences in provincial towns, and even in villages, long before the wealthy resident of a metropolitan city could command it. This, of course, was due to the simple reason that the installation of a small central station plant in minor towns required but a moderate investment and that the enterprise was often promoted by a single, public-spirited wealthy citizen; whereas in the larger communities the investment needed was considerable and the obtaining of a franchise was quite difficult. Hence the establishment of large electric light central stations was retarded until the commercial success of the new illuminant was proved by the operation of the more modest stations. Even then the installation of the larger central stations took place primarily in the business sections of the various leading cities, and long before their circuits had reached the residential neighborhoods, many of the ultra-wealthy and luxurious had put in isolated plants rather than endure any longer the disadvantages of gas.

This stage in the history of incandescent lighting has now been passed, for we find many of the newer central stations installed in districts where the patronage of private houses must constitute a large part of their income. The result is that a great many residences, especially those in course of construction, are being equipped with the electric light, and more than ever is seen the desire to break away from the stiff and conventional ideas embodied in the traditions and practice of what we may call the gas era, and to rescue decorations, pictures and tapestries from the quick detriment and ruin due to the conditions created by gas in process of consumption. Moreover there has sprung up a wish everywhere to enjoy the benefits of electric power for ventilation, pumping water, domestic elevators and the like, until at last the electrical engineer sees before him a range of work that is still very unfamiliar and that involves not a few problems. It has therefore seemed opportune to the writer to present a concrete example of what can be done in this direction, not only by availing one's self of all the later material improvements but by studying the highest æsthetic effects that may be reached with correct taste and judgment.

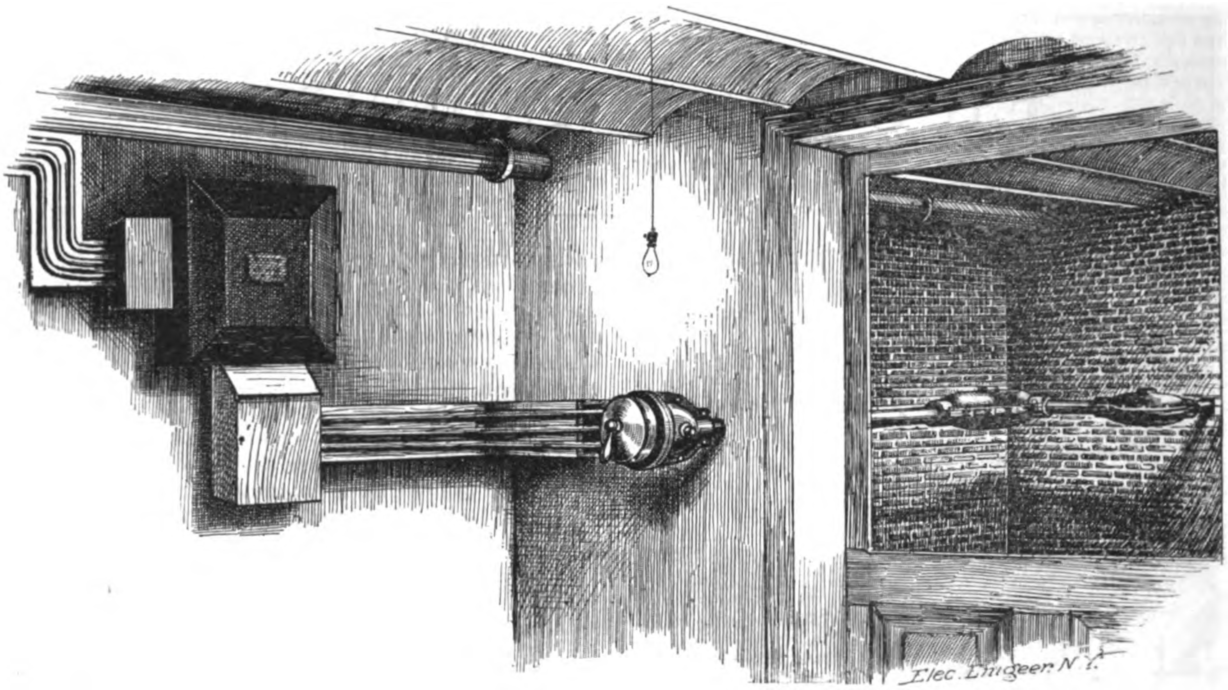
II.

The house taken as the best illustration in New York of the furthest advance in modern electrical engineering practice as applied to residences is that of Edward H. Johnson, Esq., 36 West Fifty-sixth street. Like many others in the vicinity, it derives current from the Edison mains, but there the similarity ends. As will be observed from the engraving on page 522, the street service from the standard underground Edison tubing for the three-wire system enters a vault in the basement, through the side wall, into the cellar. As the conductors come in they are first passed through a switch coupling and then to an Edison meter, which records the consumption of current for any and all purposes, hereafter described. The novel feature to be noted at this point is the switch which connects and disconnects the house and street services. It does its work without exposing any part of the conductors, the entire device being hermetically sealed; so that water might flow over it or be played against it without any effect whatever. At the same time, the entire house service can be instantaneously cut free at this point from the exterior mains, should any occasion arise. The value of such a device is apparent, and it is only natural to suppose that every house service would be safeguarded by such an arrangement.

The tubing which receives the conductors from the house end or interior side of the switch is the standard brass-covered tube of the Interior Conduit and Insulation Company; and the same tubing is employed throughout the entire house in such a comprehensive way as to render it unquestionably the finest example of electric wiring extant. It is, in fact, largely because it exemplifies so well the modern approved methods of wiring that the writer has chosen this house for special description.

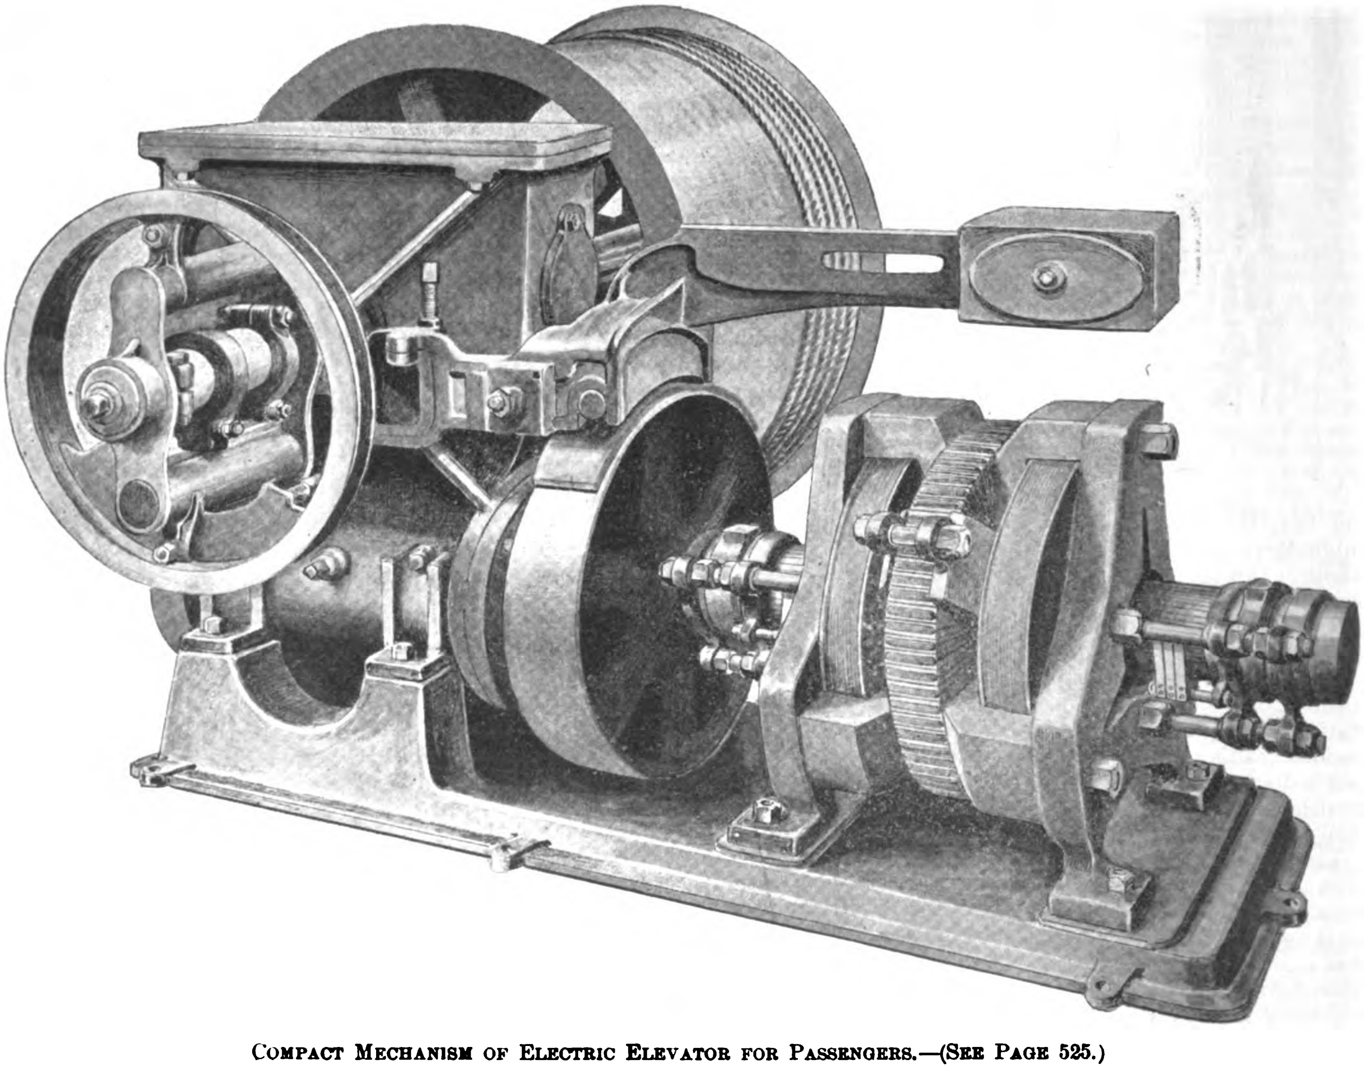


Front Door Bell, with Push Buttons Controlling Hall Lights.

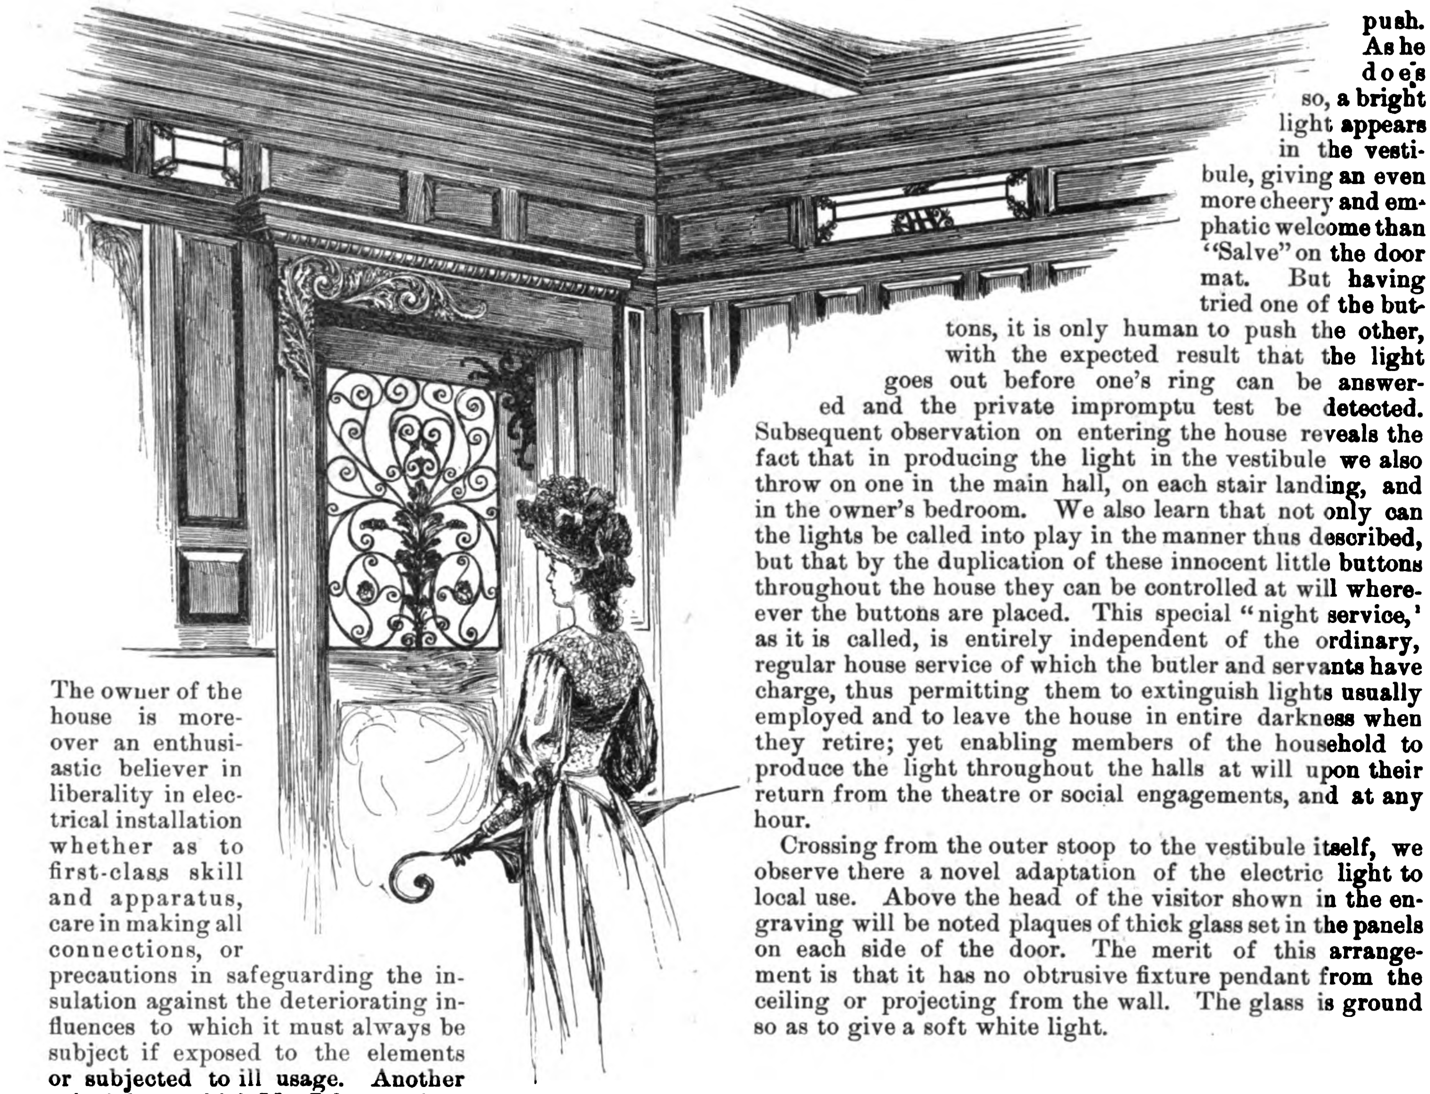


Elec. Engineer N.Y.

Entrance of Service from Street, Passing Through Absolute Cut-Off Switch and Standard Meter.



Compact Mechanism of Electric Elevator for Passengers.—(See Page 525.)



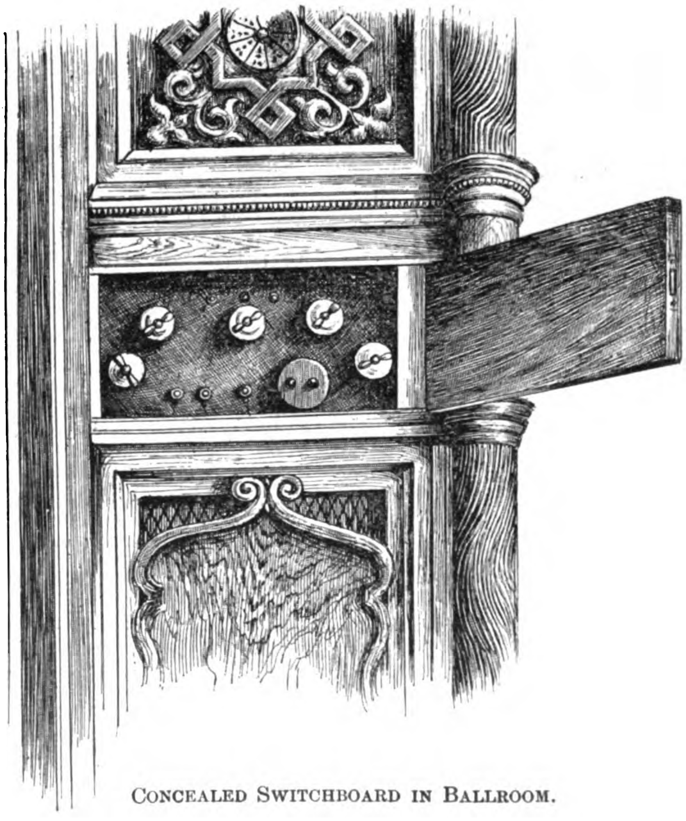
In the Vestibule.

The owner of the house is moreover an enthusiastic believer in liberality in electrical installation whether as to first-class skill and apparatus, care in making all connections, or precautions in safeguarding the insulation against the deteriorating influences to which it must always be subject if exposed to the elements or subjected to ill usage. Another principle to which Mr. Johnson gives his full support is that of extensive subdivision of the circuits, so that interference with one branch or run can at most deprive him of but a very small portion of the light normally employed in any room. It will therefore be observed here, and still more from the engraving shown later of the main switchboard upstairs, that there is apparently excessive multiplication of circuits and their enclosing tubes. But Mr. Johnson informs the writer that the extreme degree of convenience already enjoyed from having ready access to the terminals of such a perfectly subdivided and reticulated system of wires, thereby enabling him to couple any given lights in any such series as the special or momentary service of the house may determine to be most useful, has many times repaid the cost.

III.

Having for professional purposes entered the basement with the wires, we may now retrace our steps and make our approach to the main entrance as a guest, in a more conventional manner. The house was designed by Mr. Bruce Price, and those who are architecturally disposed may find more about it in the monograph on "American Architecture" by Mr. Montgomery Schuyler, recently published by the Harpers. As the eye ranges over its fair proportions, one's attention is caught by the name plate at the side of the doorway. Perhaps most visitors would not notice anything extraordinary about it, but an electrician as he pushes the button finds that the face of the plate is hinged at the top. He lifts it and two other buttons are disclosed. One of these his curiosity may prompt him to push. As he does so, a bright light appears in the vestibule, giving an even more cheery and emphatic welcome than "Salve" on the door mat. But having tried one of the buttons, it is only human to push the other, with the expected result that the light goes out before one's ring can be answered and the private impromptu test be detected. Subsequent observation on entering the house reveals the fact that in producing the light in the vestibule we also throw on one in the main hall, on each stair landing, and in the owner's bedroom. We also learn that not only can the lights be called into play in the manner thus described, but that by the duplication of these innocent little buttons throughout the house they can be controlled at will wherever the buttons are placed. This special "night service,' as it is called, is entirely independent of the ordinary, regular house service of which the butler and servants have charge, thus permitting them to extinguish lights usually employed and to leave the house in entire darkness when they retire; yet enabling members of the household to produce the light throughout the halls at will upon their return from the theatre or social engagements, and at any hour.

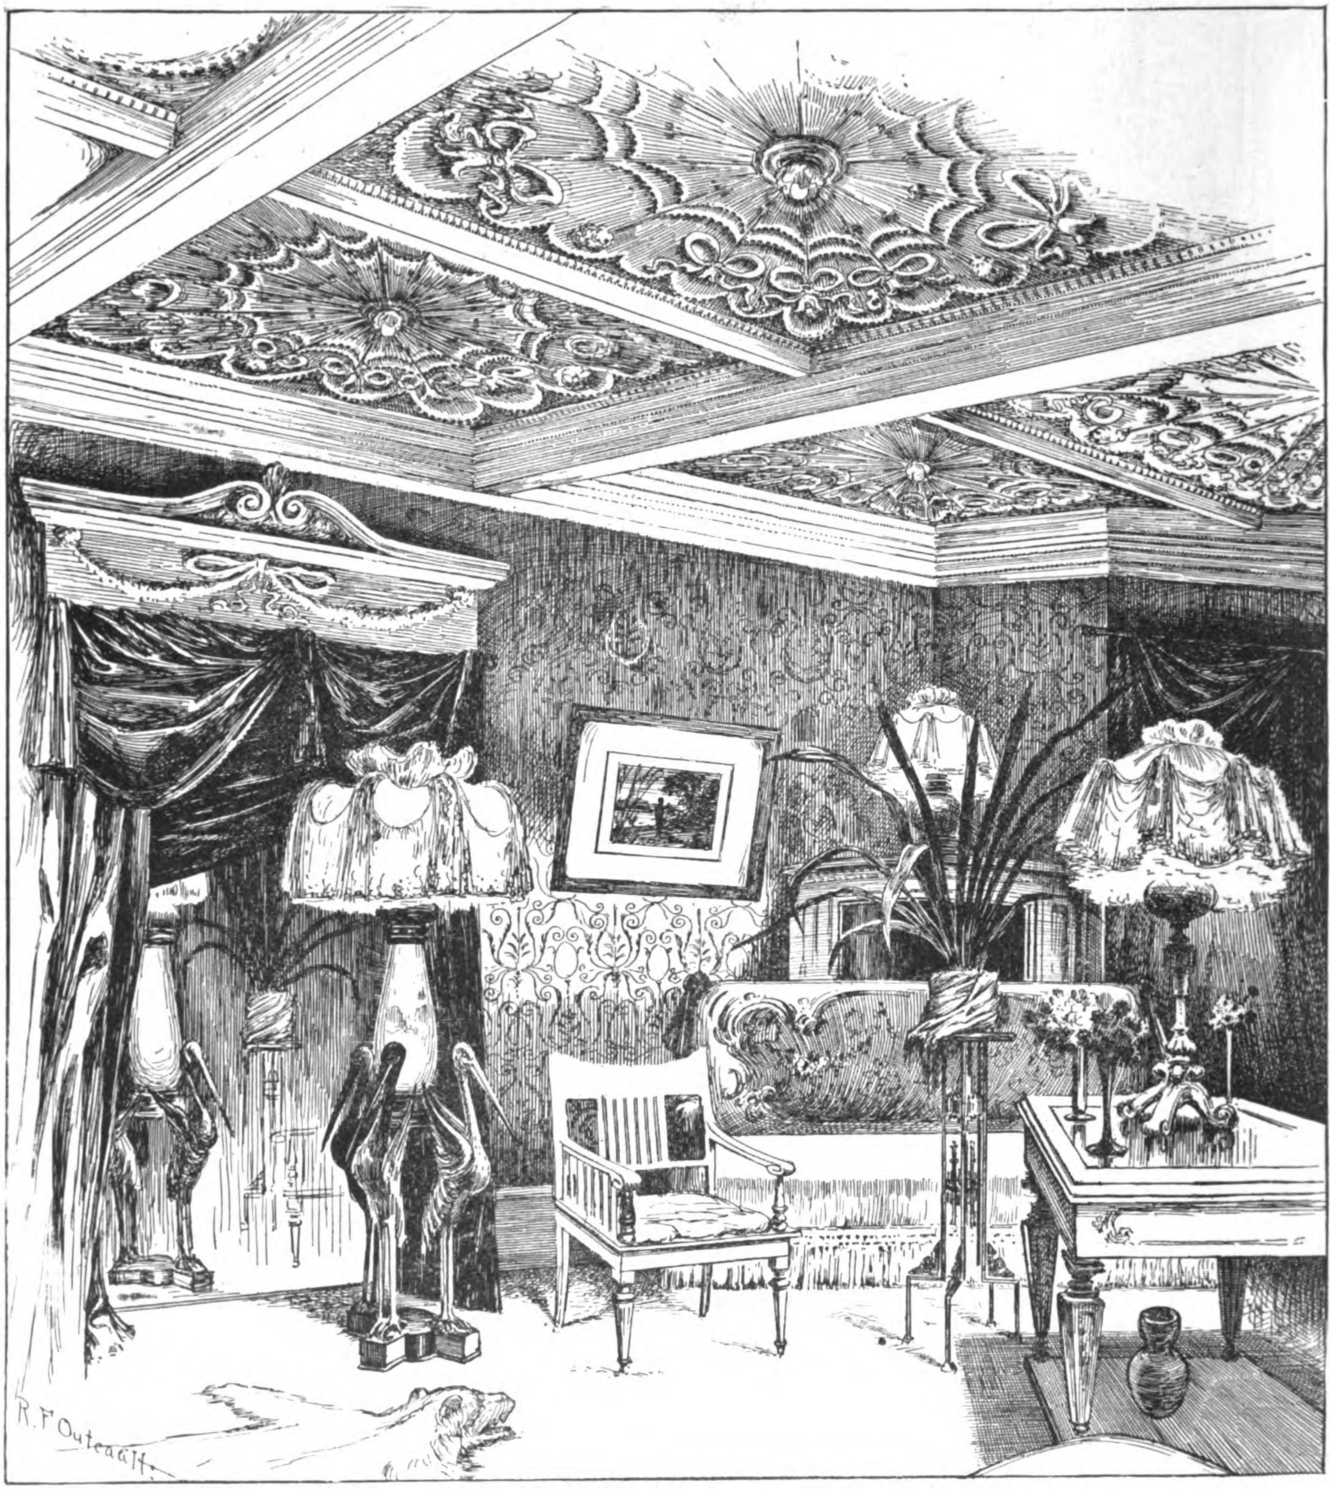
Crossing from the outer stoop to the vestibule itself, we observe there a novel adaptation of the electric light to local use. Above the head of the visitor shown in the engraving will be noted plaques of thick glass set in the panels on each side of the door. The merit of this arrangement is that it has no obtrusive fixture pendant from the ceiling or projecting from the wall. The glass is ground so as to give a soft white light.



CONCEALED SWITCHBOARD IN BALLROOM.

IV.

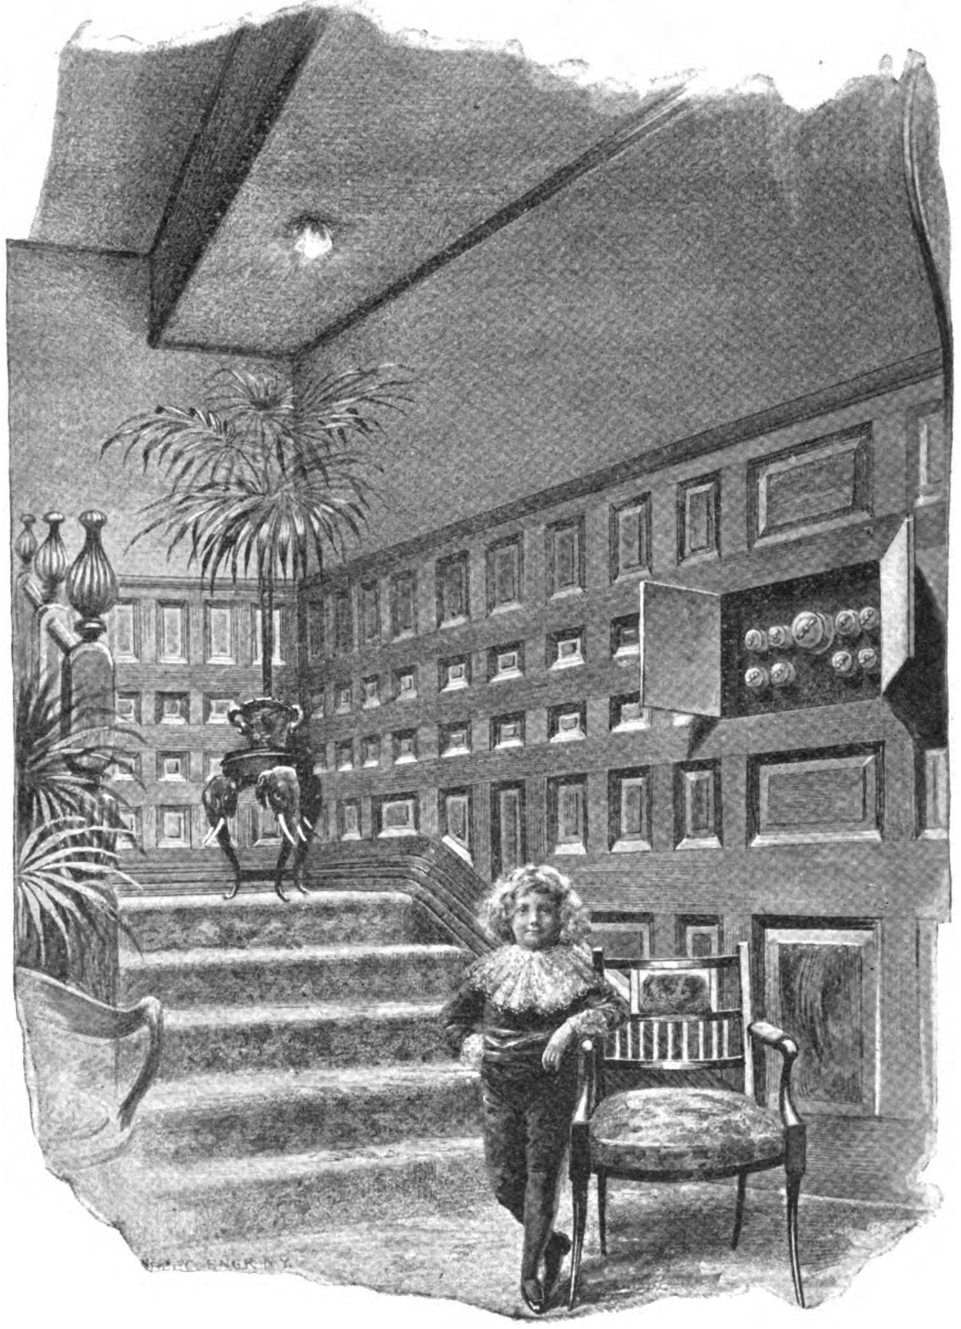
As we pass in through the front door, we find ourselves in a large hall and facing the first flight of a broad stairway set with palms. Through the portieres on the left and beyond a carven screen, we pass with our host into the ballroom, occupying a large part of the ground floor. The lighting in this chamber is perhaps the nearest approach to the conventional of any in the whole house. The decorations are in the Moorish style and the brackets, swinging lamps, lanterns, etc., are in perfect harmony. Some of the lights are set within panels in the ceiling. One or two of the fixtures are shown in the group sketch on page 526. A separate illustration is also given on page 523 of the ballroom switchboard, containing the switches, cut-outs, etc., for this room and for a very pretty, hidden music alcove. The pocket is within the woodwork of a column and is practically invisible when the door of it is closed. This method of switch concealment prevails throughout the house, and adds greatly to the charm of the electrical equipment, as does all mechanism which serves its end perfectly but is out of sight.



R. F. Outcault.

Drawing-Room Without Electric Fixtures: Lighted from Ceiling Panels and by Movable Lamps.—(See Page 526).

The lighting in this chamber is enhanced in beauty by one or two special pieces, of which the most striking is furnished by a handsome painting on porcelain of "Electricity." A female figure in the centre holds aloft the incandescent light, while two cupids carry on a long-distance telephone talk from clouds on each side of her. This appropriate picture—a souvenir of the Paris Exposition—is set in a deep box enclosed within which are a number of small incandescents, which when switched on not only bring out the subject admirably but shed a mellow light over the surroundings. Mr. Johnson thinks that a day may come when many rooms will be lighted by their pictures.



CORNER OF STAIRWAY SHOWING PANELED SWITCHBOARD.

V.

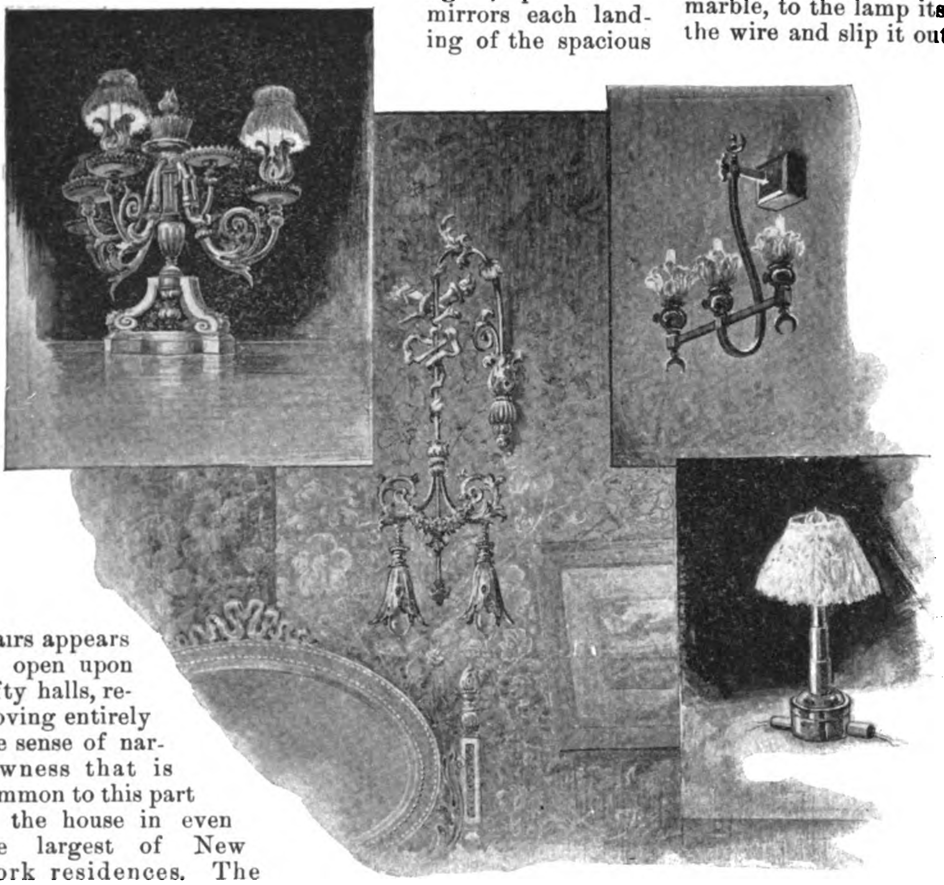
Beyond the ballroom, at the rear of the house, lies the billiard-room, where the lighting, as shown on page 526, is at the extreme of simplicity and yet warrants description. Four pieces of the brass-covered Interior Conduit tubing on the ceiling emerge radially from a central junction box, also metal-covered, and at the bent outer end of each run of tubing is a flexible cord holding a lamp with plain porcelain shade. This arrangement is not only as unpretentious as it could well be, but gives the best possible diffusion of light upon the green baize, at the same time keeping the lights well above the heads of the players as they pass around the table with their cues. It is also in such a place as this that the superior value of the electric light tells, for one thus escapes not only the cross shadows of lights on the wall, but the fierce heat that beats down from the ordinary gas or oil burners.

VI.

Through the billiard-room we can find our way to the offices that connect with the elevator and pump-room, adjoining the cellar of which a glimpse was had already. The electric pump—here of the Crocker-Wheeler make—is now a familiar object in many establishments, and does not require particular mention, though one can but admire again the pluck with which it grapples with its daily Sisyphean task and tries also to drain the Croton reservoir dry, with ceaseless throb and beat. But it is still unfortunately a rare thing to find a house that can boast of an electric elevator. Stairs that must be climbed, willy nilly, are a relic of barbarism, and now that electric power is as freely on tap as water, it is to be hoped that the day has arrived when the confirmed invalid, the delicate woman, or the feeble child, will be spared the exercise that belongs to the punishment of a convict. Here, at least, we find a passenger elevator, as shown in the illustration, novel in design both as to the motor and as to the manner of its application. The motor and gear are so placed upon an ordinary elevator as to replace the wonted pulley employed generally in connection with a steam engine. The characteristics of the motor permit of its being employed as a direct driver on the elevator drum without subjecting it or the elevator to any abnormal strain, no matter whether the speed of the elevator car be fast or slow. The compactness of the apparatus is also noteworthy in view of the restricted space that can be given up in most city houses to mechanism of this kind. Without going into further technical details, it may be pointed out that there is opened up in this direction an immense field of usefulness for electricity, one in which that servitor may be as great a boon as in lighting. Besides the direct benefit, many indirect ones are discernible. For instance, in the present case, the kitchen is at the top of the house, receiving all its supplies by means of the elevator. Not a few fine houses are spoiled by the manner in which the odors of the kitchen beset them, but with such an arrangement, now happily much more common than it was, it is possible to free one's residence from the slightest reminder of the cuisine. To this end, the electric elevator is a great help and incentive.

VII.

We may proceed now to the first floor, noting merely on our way the skilful manner in which by the combination of lights, plants and mirrors each landing of the spacious stairs appears to open upon lofty halls, removing entirely the sense of narrowness that is common to this part of the house in even the largest of New York residences. The point at which we have arrived, namely, the drawing-room, which stretches across the entire width of the building and overlooks the street from large bay windows, reveals conspicuously an emancipation from all the old ideas prevalent as to methods of lighting, and a very successful experiment in the treatment of light itself as something fluent and plastic, capable of being distributed like color for obtaining soft and harmonious effects. Perfect distribution of light is not an easy thing, and it may be questioned whether under the regime of cumbersome electroliers and massive fixtures it could ever be attained. Many salons that one goes into are brilliantly lighted, but after the eye has been hit half a dozen times with the full glare of clusters of lamps or has been worried by their reflections, the desire for outer darkness becomes rather fervent.

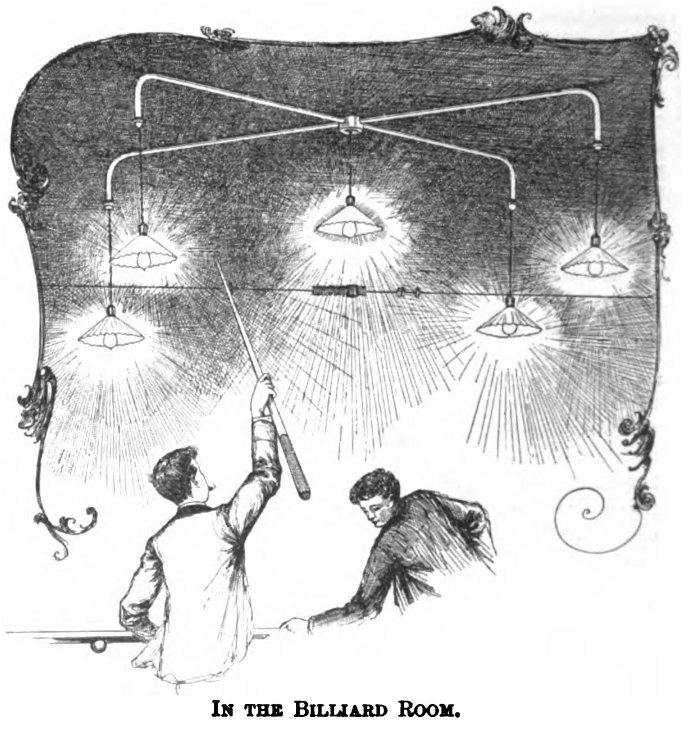


Group of Typical Fixtures from Ball-Room, Dining-Room and Bed-Rooms.

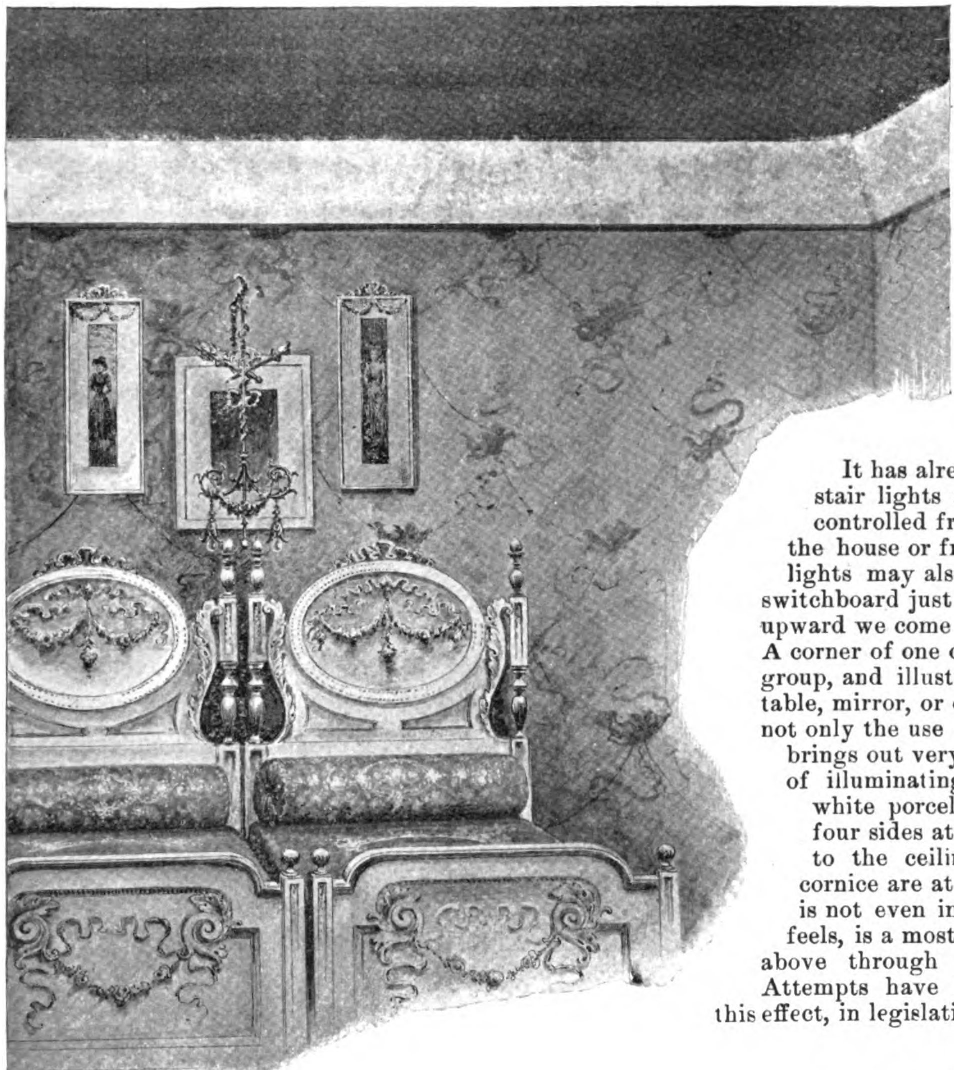
In this drawing-room, of which a picture is given on page 525, there is not a single bracket or fixture of any kind, and yet the fact of its being thoroughly lighted is accepted with as little thought as one greets midday sunshine. The decorations are in white and gold, and the frosted lamps set in the ceiling panels, in delicate tulip cups, do not strike the eye individually. We have not lights, but light. In addition, each of the ornamental lamps disposed casually about the room carries not only a light under its canopy but one within the body of the hand-painted vase. Hence the whole lamp is luminous, but with a charmingly diffused and pervasive effect, especially when enhanced by mirrors. Curiosity is naturally aroused as to the way in which the stork lamp, for example, or that on one of the onyx tables is reached by the circuit. The explanation is simple. It will be remembered that every wire—every inch of it—is within the safe enclosure of an insulated tube. Hence it may be drawn in or replaced at will without the disturbance of a single thing on the floors, walls or anywhere else. The wire comes up under the table, for instance, either at the side or through a central leg, and then is carried through an almost imperceptible hole in the onyx, or wood, or marble, to the lamp itself. Nothing is easier than to release the wire and slip it out, and then furniture can be moved, carpets be taken up, and any other process in the domestic economy can be gone through without the slightest fuss or inconvenience.

VIII.

The lights in the drawing-room are controlled from the large switchboard shown in the sketch of the stairway, and illustrated more in detail in a separate cut. As will be seen, the situation is eminently accessible, and yet when the door is closed, the mahogany paneling appears to be intact. This board controls also the lights in the library that adjoins the drawing-room, where the same methods are practically followed. When open, the board is an ornamental and highly finished piece of work, with polished slate base and all the details in brass. The Johnson vicelock switches are used, giving instantaneous and emphatic manipulation of the circuits; and the tubes with the wires are all brought to the face of the board. In other words, it is as though the back of the board had been made the front, rendering inspection a ready and simple thing at any moment. The board is remarkable in the range of control it allows of a large subdivision of circuits, all of which may be grouped and governed from it as though they were going through a series of intricate evolutions; and yet the board is barely a



In the Billiard Room.



A Bed-room Lighted by a Decorated Porcelain Cornice.

couple of feet square and would usually serve for only half a dozen lights.

This stairway opens, as already stated, upon the library, one of the most charming features of which is shown in our sketch of the "Business Nook." There is a good time coming when all of us will be able to put the telephone into our homes, and thus at any moment be in the world though not of it; and when that time arrives we shall do well to follow the example here set us. The wall bookcase alongside the cosy fire opens up at a touch and shows an attractive desk, where stands a long-distance telephone, district messenger box, and any other appliance that like the lamp of the Arabian youth will bring the tidings or service we call for. Our business with the public attended to, the case closes up noiselessly, and the world is once more barred out and cut off.

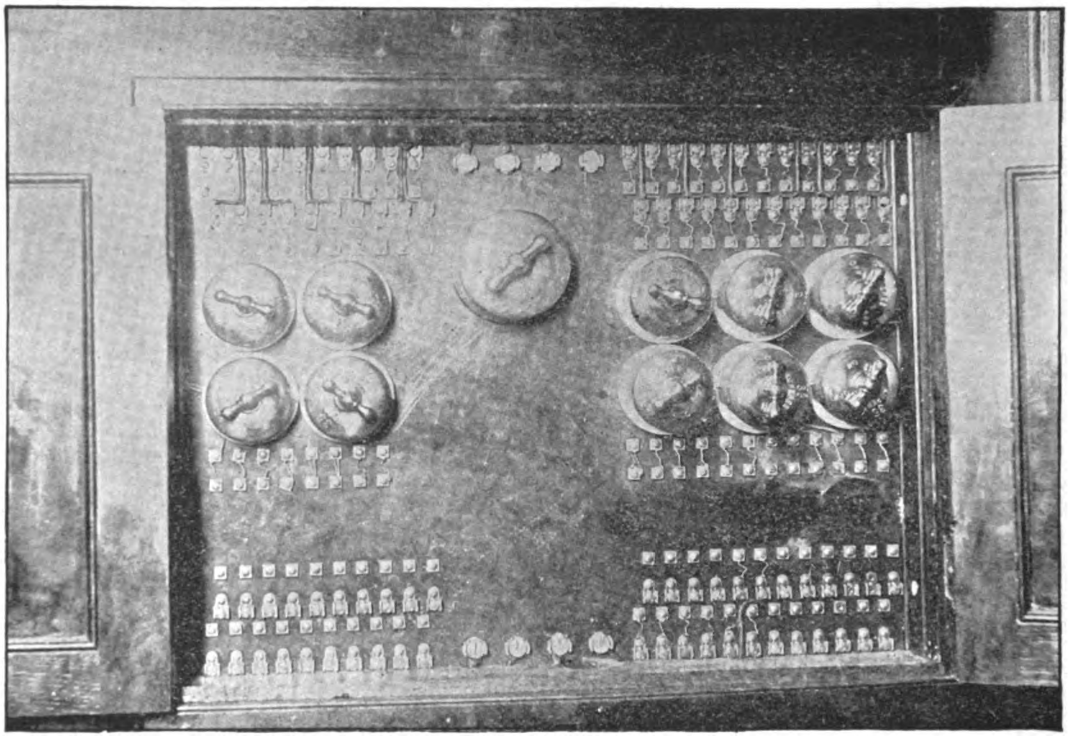
Immediately adjoining the library, is the large dining-room at the rear. Here the lighting is done by ceiling and side lights, but the circuits and tubing have been so arranged that the table may be specially lighted at any time with added and novel effects. An instance of this flexibility was afforded recently by a luncheon party given by Miss Johnson on the occasion of her graduation, when a large number of her companions in the graduating class gathered around tables arranged in a long double curve. The wires were led up to a number of special little frosted lights mounted on stands made very ingeniously out of sections of Interior brass tubing; and one of these stood by each cover. At the end of the luncheon the circuits were cut and each guest carried off her lamp as a souvenir. This little device is shown to the right in our group of pictures on page 526. The novelty of this style of "favor" has many points of recommendation, and if only for the welfare of the lamp industry the writer would be glad to see the practice extended, so that no young lady would go to a "pink lunch" or dance the German without expecting to carry home with her as a trophy one of the "bright lamps that shone o'er fair women and brave men."

IX.

It has already been explained that the hall and stair lights are on a separate circuit that may be controlled from the name plate at the entrance to the house or from the owner's bedroom; and these lights may also be thrown on or off from the main switchboard just shown on the stairs, following which upward we come to the bedrooms on the second floor. A corner of one of these rooms is shown in the fixture group, and illustrates the arrangement at a dressing table, mirror, or cheval glass. The other sketch shows not only the use of lights at the head of the bed but brings out very clearly the original method adopted of illuminating the room as a whole by means of a white porcelain cornice, which runs around the four sides at a slight angle inward from the wall to the ceiling. The lamps placed behind this cornice are at regular intervals, but their position is not even indicated. All that one sees, or rather feels, is a most delightful diffusion of the light from above through this delicately decorated porcelain. Attempts have been made on a large scale to obtain this effect, in legislative halls and other places of assembly,

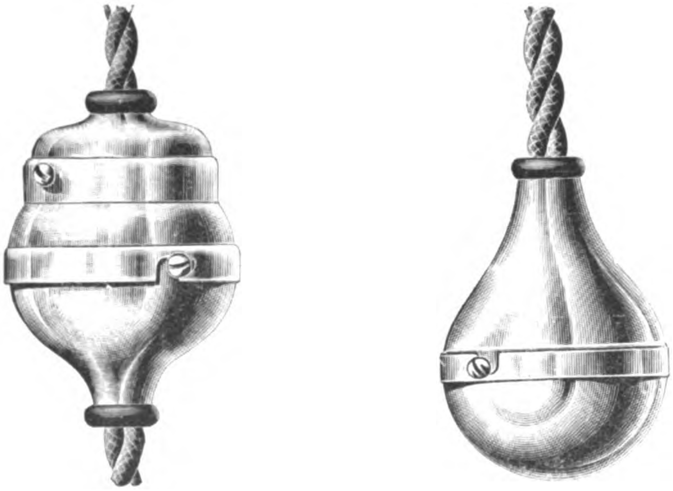
The "Business Nook" in the Library.

where the light is shed through a semi-transparent ceiling, but the result is harsh and crude to a degree as compared with what is seen here. These pictorial panels of porcelain give an ideally lighted bedroom, having seen which it is impossible to believe that an equal result can be attained in any other way. At the same time, the pendants controlling the wall lights above each bed enable one to read through the wee sma' hours, and extinguish the light at will, without moving and without fear of dropping off to sleep with the attendant risk of fire, as would be the case with gas or oil.



Details of Main Switchboard, on the Stairway.

While on this floor it is worth while to note that every bath-room and clothes closet has its pendant light, with a clever little "pull" switch, throwing the light on or off by the merest motion of the wrist. Mr. Johnson has also arranged some of these closets so that the opening of the door switches on the lights while closing it turns them off. The idea is an excellent one deserving of further application. The little switch here shown is also used as a pendant from the centre of electroliers, dispensing with key sockets and affording the readiest means for controlling the current on a single light or on a group. In one or two instances, Mr. Johnson has it arranged as shown in the other engraving, midway in the flexible cord of a pendant. This is done by simply cutting the cord and attaching the terminals to the binding screws provided for the purpose. With this again, the lights are turned on and off by a slight pull.



"Pull" Switches for Flexible Cord Pendants.

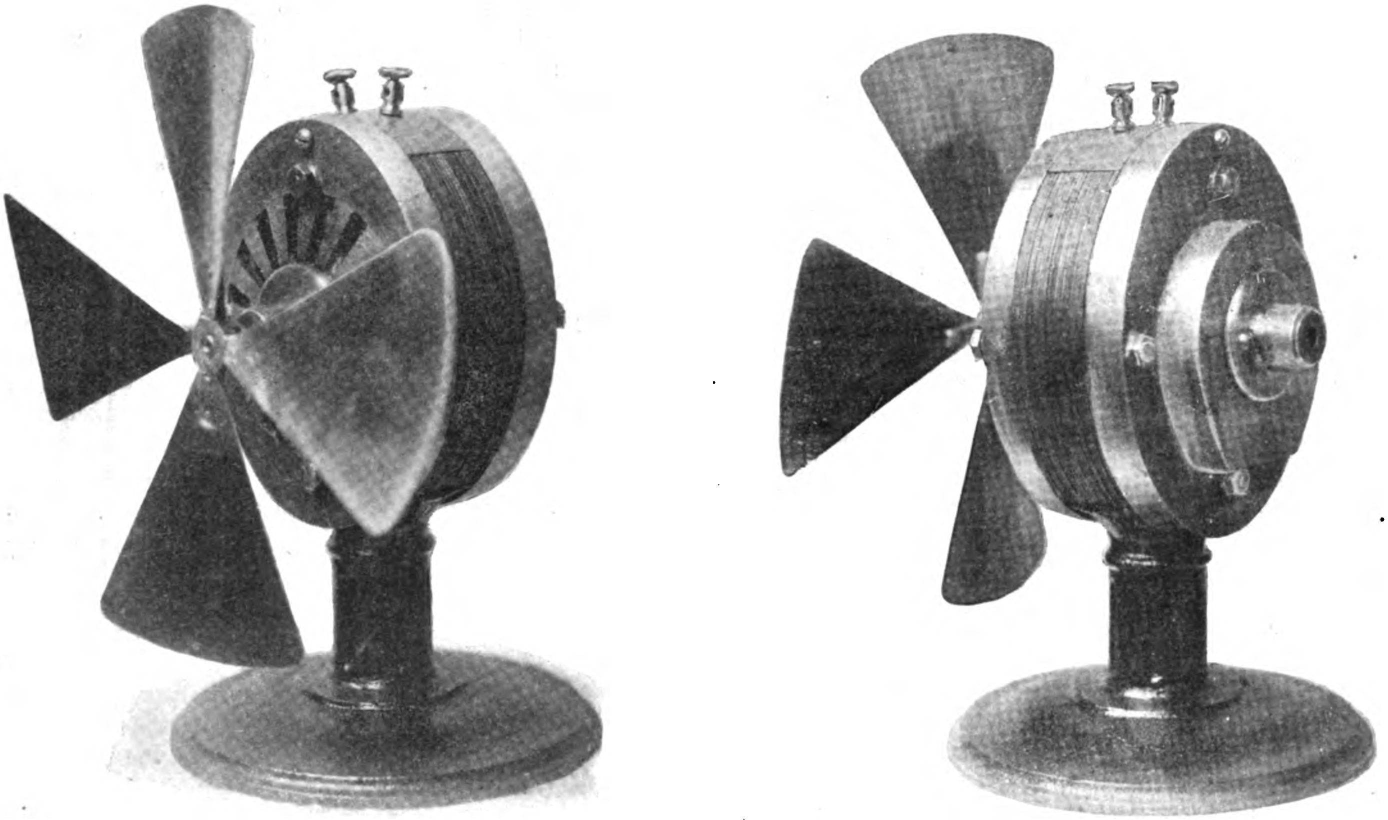
X.

At this point we may suspend the tour of observation, for while in the remaining floors above, the same attention to detail is seen, whether in sleeping apartments, nursery, school-room, kitchen or pantries, the devices are more familiar and time-honored. One must not fail, however, to mention that the central square formed by the stairs in the upper part of the house is beautifully lighted by a large stained glass skylight, which, owing to the lights concealed within it, is a prettier sight by night even than by day. The stairs themselves are masked by a high mahogany grille, but are brilliantly lighted in this way, not less than the broader flights below with their palms and draperies.

It is not to be supposed that all the happy and successful innovations in the use of electric light and power that have been described, are the production of a few hours or a few days. It is not to be supposed that these things can be had without money and without taste. Nor is it to be supposed that every wealthy citizen who wanted to be original in his methods of illumination could do what has been accomplished here. But it happens that in this case, the owner of the house, with abundant means to try such experiments, is a man of quick invention and a very long experience in electrical engineering. Mr. Johnson is an ardent believer in certain principles relating to the electrical arts, and here in his own home he has given the fullest expression to his convictions and the freest play to his taste and genius. As a consequence we have an object-lesson of the first importance, the study and mastery of which may teach us all there is to be known in the best modern methods of utilizing electric light and power in the House Beautiful.

THE GUTMANN ALTERNATING CURRENT FAN MOTOR.

With the approach of the heated term, the refreshing breeze of the little electric fan motor is looked forward to by many who have heretofore been unable to secure ventilation in small and confined apartments. Those who are within reach of, or distributing, the alternating current, especially, will be interested in the description of a new fan motor designed to operate on alternating circuits, and now being brought out by Mr. Ludwig Gutmann, of Pittsburgh, Pa. In designing this little motor, Mr. Gutmann has had in mind particularly the difficulties which have been encountered due to the fact that the brushes of such motors required frequent adjustment owing to the delicate contact necessary in order to avoid excessive loss due to friction at the commutator. When trouble did develop it was frequently aggravated by the meddling of unskilled persons.



The Gutmann Alternating Current Fan Motor.—Front and Rear View.

The problem of obviating this difficulty may be attacked from either a mechanical or an electrical standpoint. The former plan was adopted by Mr. Gutmann, and led him to the construction of the motor shown in the accompanying illustrations. The inventor has set himself the task of building a simple alternating current motor, requiring little attention, whose brushes could not get out of adjustment, and would be difficult of access to the unskillful user.

The motor belongs to the induction type, having its field coils permanently connected to the two terminals of a circuit or lamp socket of 50 or 100 volts, while the armature has no electric connection with its field. The armature is of the drum type located between the two field poles, and is provided, as usual, with a commutator on which rests a brush of peculiar construction. This is a modification of the brush patented by Mr. Gutmann, in which a low resistance conductor is placed between two conductors of high resistance, thus presenting a good conductor in contact with the commutator, and a high resistance contact on the side where the segments leave the brush.

The brush is of horseshoe shape subdivided in a plane at right angles to the axis of the armature, and supported by a bolt or arm above the commutator. About half way between this arm and the free ends of the brush are internal projections, supporting carbon blocks on one side and making contact with the commutator. To insure proper contact at all times the horseshoe brush is divided into two parts and hinged on the support, at the opposite side of which the tension is applied by means of a spring. The brush cannot be shifted, and as long as there is anything left of it the motor will operate. The brush is designed to operate by gravity alone, but for the fan motors it has been thought advisable to add the spring. It is intended to omit the latter on the larger machines.

A glance once a fortnight is all the inspection required by this motor. The brush is encased out of sight and out of reach of ignorant or meddlesome persons, the bearings are self-lubricating, and the liability of getting out of order is reduced to a minimum.

PRIZE ESSAY ON THE TRANSMISSION OF POWER BY ELECTRICITY WITH SPECIAL REFERENCE TO ITS APPLICATION TO MINING.

An Alumnus of the School of Mines of Columbia College of New York has offered a prize of $100 for the best essay on the above subject that may be presented by a graduate of the school. The essays must be sent to Prof. W. P. Trowbridge on or before Nov. 1, 1892. President Seth Low will appoint a committee to examine the essays and award the prize. The successful essay will be published in the *School of Mines Quarterly*.

Mr. J. Elliot Smith, the superintendent of fire-alarm telegraphs of New York, has been appointed superintendent of fire-alarm, telegraph and appliances in the new Building Department.

VOL. XIII. NEW YORK, MAY 25, 1892 No. 212.

From a want of knowledge of the state of science and a due consideration of the proper time and place, many ingenious minds have wasted their energies in fruitless labor, waged with fortune an unequal war, and sunk into the grave the victims of disappointed hopes.—Joseph Henry.

ELECTRIC LOCOMOTIVES FOR SHORT STEAM ROADS.

IT must be evident to all who watch the development of electric railway work that the point has been reached at which the substitution of electricity for steam on short steam railroads ceases to be a matter of discussion and enters the stage of practice. The departure is by no means as strange and revolutionary as it will certainly appear to many people, for not a few of the larger street railways are doing work with their electric cars more than equivalent to the demands that are likely to be made anywhere except on long steam roads. In Boston, for example, or Cleveland and St. Louis, or between St. Paul and Minneapolis, the electric service is handling a passenger traffic much heavier than that on a large number of the "commuter" steam roads around New York, Philadelphia or Chicago. The main difference, after all, and that not a small one, is that each of the electric street cars is its own motor and is almost always restricted to passenger traffic, while in the new work, just beginning, the trains, both passenger and freight, are to be handled by heavy locomotives, following in many respects the best precedents that the magnificent art of steam locomotive-building can furnish.

After all, the stages of evolution by which we have attained the present point in electric railway work have been comparatively slow. Several years ago, Mr. Leo Daft built an electric locomotive work for Elevated Railway experiments in this city. The motor was of about 125 h. p. and behind it the present writer more than once made the best speed he has ever seen on the Manhattan system. In 1886, Mr. Frank J. Sprague made some very interesting experiments on the same road with trains of individual motor cars, and also began the construction of a double bogie truck car, each axle driven by a 75 h. p. motor, making a 300 h. p. equipment, and weighing with the car and passengers about 30 tons. In 1886 also, Messrs. Bentley & Knight and the Rhode Island Locomotive Works made plans for a 670 h. p. electric locomotive. These plans were published in Martin & Wetzler's work on the electric motor, at the time, but, we believe, were never put into execution. More lately, the City & South London underground road has been operating with electric locomotives of about 100 h. p., made up by a 50 h. p. motor driving on each axle; and a few months ago, the Thomson-Houston Co. built a locomotive of about 125 h. p. for freight service at Whitinsville, Mass. That locomotive, on trial, handled a train of 4 to 6 heavily loaded cars, or an aggregate load of 200 to 300 tons, at a speed of 5 miles an hour on a level.

It might be said, with truth, that all this preliminary work does not touch the main issue, the practical substitution of electricity for steam on a regular steam road,—but the new day has arrived, and we are glad to make note of two highly important events marking the initial steps of the change. Perhaps Mr. Henry Villard, the president of the North American Company, always a shrewd and enthusiastic believer in the possibilities of electric traction, deserves the credit for making the first contract for electric locomotives on a steam road. He has been anxious to improve the facilities around his Northern Pacific terminals in Chicago, and more than a month ago, it is understood, made an agreement with Mr. Sprague for an electric locomotive of not less than 700 h. p. to handle the traffic. The Thomson-Houston Company will also, it is said, build a locomotive of similar capacity for the same work.

Following quickly upon this action of Mr. Villard, comes the news of the determination of the Baltimore & Ohio Railroad Company to equip the tunnel of the Baltimore Belt Railroad with electric locomotives and the necessary power plant. Although various reports have been published as to the details of this work, it was not until the close of last week that the details of the contract were finally settled. As far as can be ascertained, the contract involves the building, for delivery early next year, of three 80-ton locomotives, which are to develop, approximately, a drawbar pull of 31,000 pounds at 15 miles an hour. A station of about 2,500 h. p. will be installed with four units and direct-coupled engines and generators. This station will be midway in a run of 12,000 feet. The maximum work required of each locomotive in developing this drawbar pull is to move a 1,200-ton freight train over a grade of about eight-tenths of one per cent. at 15 miles an hour; and, in passenger service, to move a 500-ton train at 30 miles an hour over a similar grade. Each locomotive will also be expected to serve as a reserve or assistant engine for the regular steam locomotive just outside the tunnel, when the latter is hauling a freight train up a grade of $1\frac{6}{10}$ per cent. All told, there will be about 200 trains a day of each class. The tunnel is also to be lit by electricity.

Our readers will at once see that in Chicago and Baltimore electricity is to be put to some of the heaviest traction work yet encountered, and they will share with us the conviction that the new motive power will be more than sufficient for the demands thus made upon it. Personally, as New Yorkers, we could only wish that the New York Central saw its way to taking part in this work, so that its tunnel leading to the Grand Central Depot might be redeemed from its present mephitic foulness and gloom. It seems to us that Mr. Twombly, who has now happily transferred to electrical work a part of his time and energy, as an executive officer of the General Electric Co., must have it borne in upon him that while he is thus making contracts with roads South and West he might do a good stroke of business and earn the gratitude of every citizen of New York as well as everybody who comes in over the great Central system, by making the Harlem tunnel as sweet and cheerful, by the aid of electricity, as Fifth avenue is on one of these bright May days.

THE ELECTRIC CLUB OF NEW YORK.

The new Board of Managers of the Electric Club of this city in taking up and continuing the special work of its immediate predecessor in straightening out the finances of that institution is showing an activity and devotion that should entitle it to the fullest support and sympathy of the entire electrical community. Not only has it already done wonders in lifting the load of indebtedness, but it has begun to rally support to such an extent that 22 new members have been admitted during the present month. This is a bright augury, and if every member saw to it that he brought in one eligible candidate, the club would soon be in a very prosperous condition. As a social institution, a common centre for a large variety of interests, the club has done a great work and still has a well-defined mission. Its purpose is of the highest and the fine old house in East Twenty-second street has seen many a bright and pleasant gathering. Next year we shall have a large influx of electricians from abroad, and steps must soon be taken for their appropriate reception. In this work, as in many other things, the Club and the Institute might well join their forces. We are glad to learn that the club will celebrate its present cheering outlook with an entertainment on Friday night, and trust that the attendance will be the largest ever seen within its hospitable portals.

ELECTRIC HEATING.

Our contemporaries devoted to the recording of advances in engineering work, have for some time found much interesting matter to occupy their columns in the application of electricity in various forms. Among these applications, electric heating and electric heaters have of late been given special prominence and have, in more than one instance, been the subject of critical discussions as to their efficiency. Readers of this journal may recall our comments on an article of this nature, which appeared in our excellent contemporary, *The Engineering News*, some time since. That paper attempted to show, that considering the low heat unit efficiency of a system of electric heating, its application, even on the smallest scale, was practically out of the question. We are glad to note, however, by the appearance in its columns of an article on electric heaters, that this useful apparatus is now shown to have a field comparatively narrow, though it may be almost infinitely long. When there is daily evidence of the adoption of electrically heated tailors' "gooses" by the proprietors of the so-called sweating shops, "it is reasonable to believe that electric heating can be used with decided economy." And the writers also go on to show that wherever the conditions prevent the use of the oil or gas stove, and preference is given to appearance and convenience rather than to economy, it may come into play. This is exactly the position we have maintained on this matter from the beginning, holding that there are many instances and conditions which make electric heating desirable and economical.

CARBON.

Modern electrical engineering, and this term is here used in a comprehensive sense, is so largely dependent upon copper as the transmitter of the electric impulse of whatever nature, be it for lighting, power, telegraph or telephone, that one scarcely realizes the important position which another material has assumed in the same art. This material is carbon, of which it may truthfully be said that, without it, both electric lighting and telephony would still be largely in the experimental state. For, despite the obvious short-comings of carbon in the form of the pencil employed in the arc lamp, or of the filament as we find it in the incandescent lamp, it still holds its own in those fields against all comers. And while we have also been promised substitutes for carbon in the telephone transmitter the fact remains that carbon is used to-day, and it is safe to say that if a better material were available it would be used in practice. That carbon still has a field before it in other electrical applications is well illustrated by the fact that we note a new use for it, and this time in a direction which would hardly have been expected. Cable telegraphy so rarely experiences an advance that any improvement worthy of the name is deserving of special notice ; hence the new carbon relay for submarine cables, described by Mr. Charles Cuttriss on another page, will be of interest, as it embodies a construction which for the first time permits of cables a thousand miles in length being operated by relay without necessitating local hand repetition.

The Kelvin.

Electrical engineering has given opportunity for the coining of numerous words and phrases but that there is still a desire to avoid circumlocution in electrical literature is shown by the recent formal adoption by the English Board of Trade of the term "Kelvin," to express the Board of Trade unit of electrical energy, 1,000 watt hours. As a compliment to, and a recognition of the electrical services, of Lord Kelvin, the new term will, without doubt, be speedily adopted. There has been some complaint against the coining of so many new words in electrical nomenclature, but we are among those who believe in brevity, when clearness is not sacrificed thereby ; and in the present case there can certainly be no confusion with any other unit thus far proposed. It may be easy to make fun of these units, but they will outlive the joke.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—V.[1]

BY

A. E. Kennelly

POTENTIAL DISTRIBUTIONS (*Continued*).

FIG. 8 represents a plane section through the axis COD of a circular loop of wire AB carrying a current[2] and the traces of 24 equipotential lines. If the diagram be rotated about the axis COD, these lines will generate the corresponding system of lenticular equipotential surfaces. These commence at the surface of the wire, and are all finite except the plane AOB which may be extended indefinitely. The case applies practically to a single-ring tangent galvanometer, and in order to make the particular equipotential surfaces here indicated correspond to successive integers, the current in the ring must be 1.91 C. G. S. units or 19.1 amperes, circulating clockwise as viewed from C. The M. M. F. or total P. D. in the magnetic circuit will be $4\pi \times 1.91$, or 24 ergs per unit pole, and the surfaces are marked from + 12 to — 12, down grade in the direction of the arrow.

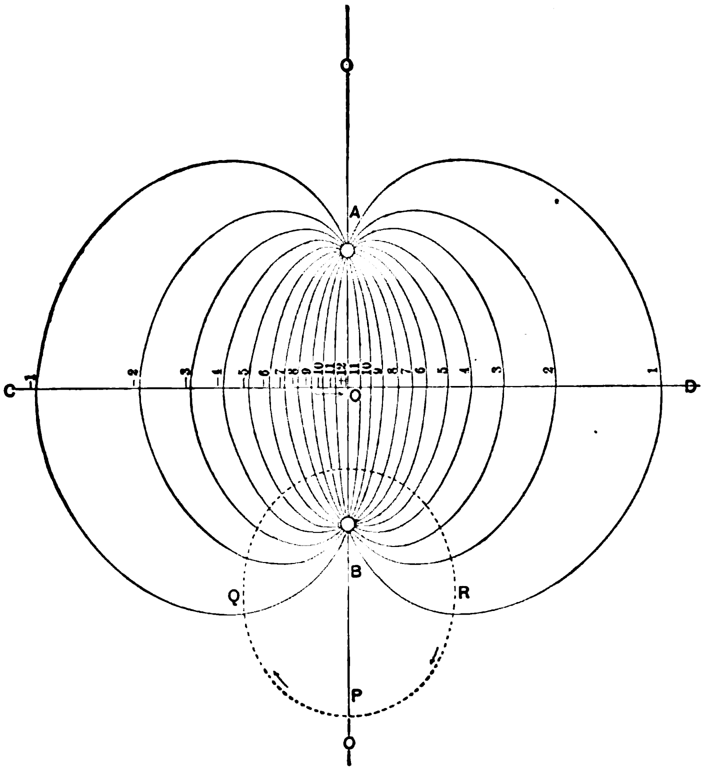

FIG. 8.

We have already seen that each equipotential surface must be so described, that from any point in it the solid angle subtended by the ring is the same. While this rule accurately defines the potential at any distant point from which the ring appears as a mere circular filament, it needs modification for those points nearer the ring where the solid angle subtended by its outer edge and inner edge differ sensibly. At these shorter ranges, it is necessary to suppose the ring divided up into a suitably large number of smaller and filamentary circles, each carrying its due share of the current. The sum of the solid angles multiplied by their current for all these elementary rings will give the resultant potential. The same reasoning applies to a coil of any shape made up with separate turns of insulated or uninsulated wire.

Starting from any point P on the plane AOB outside the ring, the surface of the ring vanishes to the eye of an observer at this point, so that the solid angle and potential are here both zero. As we proceed down grade along the dotted line of B cutting the successive equipotential surfaces at right angles, the ring opens into view, and the solid angle,—its area of projection on a unit sphere—increases, but the direction of the current appearing clockwise, the potential is negative. It continues to increase numerically until the interior plane AOB of the ring is reached, when its projection will embrace just half the surface of a unit sphere, making the solid angle 2π, and the potential $-2\pi c = -2\pi \times 1.91 = -12$. The instant, however, that the central plane is passed, the aspect of the ring changes, and the current appears to circulate counter-clockwise. The potential is now positive and + 12 (the solid angle being still 2π). At the passage of the median plane, there has been an abrupt cyclic elevation of potential of $4\pi c$, without any discontinuity in the gradient on either side of the ascent.

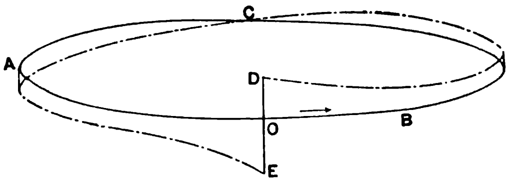

FIG. 9.

This distribution of potential is depicted diagrammatically in Fig. 9. ABC is the perspective view of a horizontal loop, an elementary magnetic circuit and individual line of flux such as PQR in Fig. 8. The vertical distance of the line DCE above or below, marks the potential at each point of the circuit. The gradient of the line DCE has everywhere a definite value, and numerically equals the intensity *B*. At the point O corresponding to the interior plane AOB of Fig. 8, the potential rises abruptly from E to D through $4\pi c$ units, the gradient just before F, and just after D being the same.

This is precisely analogous to the conditions that would be established if ABC were a galvanic instead of a magnetic circuit, with a battery of $4\pi c$ volts at O, except that galvanic circuits are usually closed through insulated wires of uniform cross-section and conductivity, that impose a uniform gradient or drop in electric potential. If the circuit were metallic—not completed through the ground—the potential would start at the copper pole of the battery with a value of $+ 2\pi c$ volts and would fall in one circuitation to $- 2\pi c$ volts at the zinc pole, assuming that the internal resistance and consequent drop of potential in the battery were negligible. There would be a cyclic elevation of potential in the battery of $4\pi c$ volts.

Fig. 10 represents a similar magnetic circuit ABC threading two rings of wire, each carrying a current of *c* units. The M. M. F. in the circuit will here be $2 \times 4\pi c$ or $8\pi c$ ergs per unit pole. There are two discontinuities of potential, at B, and at D, while the average gradient is twice as steep as in the preceding case. It will be noticed that all discontinuity might be avoided if the potential

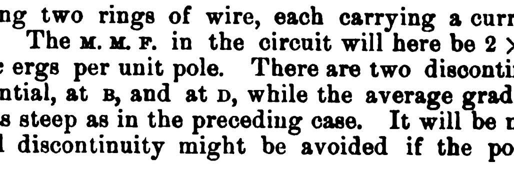

FIG. 10.

---

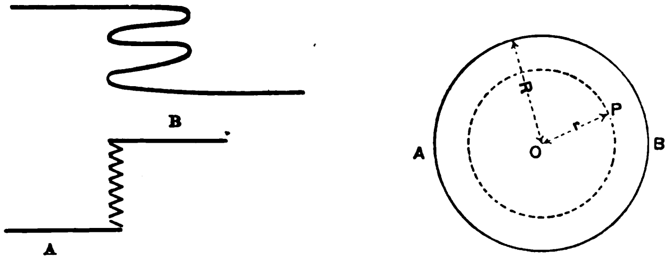
[2] J. Clerk Maxwell, *Electricity and Magnetism*, Vol. II., Plate xviii.

line at F continued along the dotted line towards G instead of rising to the new level, but by pursuing this course, it would continue to generate a spiral whose successive convolutions would be $8\pi c$ units apart. The potential would then be continuous but multiplex. Similar conditions would apply to the galvanic circuit, but for the fact that all electric potentials are conventionally measured relatively to that of the ground in the vicinity, which precludes multiplex values and makes cyclic discontinuity the necessary alternative.

In passing along a magnetic circuit through the spires of a coil or solenoid conveying a current c, there is a cyclic elevation of potential equal to $4\pi c$ at the plane of each spire. For two spires the elevation would evidently be of the type shown in Fig. 11; for a larger number of closely associated turns, the line of elevation instead of being abrupt would appear to have a definite gradient, A B, Fig. 12, namely, $4\pi n c$, n being the number of turns per centimetre of circuit. This explains why the flux, in Figs. 4 and 5, of Chapter III appears to move up grade, contrary to rule, within the solenoid and sphere. The apparent anomaly is due to the continuous superposition of small cyclic elevations, and the potential may be considered to descend uniformly, but to be increased by $4\pi n c$ per centimetre of coil. A similar apparent reversal of current against potential takes place in a series of cells supplying a galvanic circuit.



Figs. 11, 12 and 13.

Returning to Fig. 8, the solid angle at any point on the axis C O D distant x centimetres from the centre O, is readily found to be $2\pi\left(1 - \frac{x}{\sqrt{x^2 + r^2}}\right)$, r being the radius of the circle A O B, and the cross-section of the wire being so small that the current may be considered filamentary without practical error. The potential is therefore

$$P = 2\pi C\left(1 - \frac{x}{\sqrt{x^2 + r^2}}\right).$$

The gradient of this or $-\frac{dP}{dx}$ is $\frac{2\pi C r^2}{(x^2+r^2)^{\frac{3}{2}}}$, and numerically equals the intensity B at any point on the line C O D. At the centre O where x is 0, B becomes $\frac{2\pi c}{r}$. A ring set in the magnetic meridian, and employed as a tangent galvanometer superposes on the earth's intensity in the line A O B, the intensity $\frac{2\pi c}{r}$ at O directed along C O D, and a small magnetic needle placed there will set its magnetic axis along the resultant of these two rectangular fluxes. If θ be the angle of deviation we must have

$$\frac{\text{coil's intensity}}{\text{earth's intensity}} = \tan\theta = \frac{\frac{2\pi c}{r}}{H},$$

H being the earth's horizontal intensity; from which $c = \frac{H r \tan\theta}{2\pi}$ the usual tangent galvanometer formula.

The solid angle and potential of the ring cannot be so simply expressed for a point not situated on the axis of the ring. Although there are several methods for evaluating them, all involve the use of convergent series whose terms have to be summed until the desired approximation is attained.[1] It is evident from the figure, however, that on the median plane A O B, within the ring, the intensity is a minimum at the centre O for the equipotential surfaces — 11 and + 11 are furthest apart at that point; yet as regards the axis, B is a maximum at O, for along O C or O D the surfaces separate out as they recede from the median plane.

The total flux threading the wire, or the surface integral of B, is also a complex expression. It increases directly with the linear dimensions of the loop, for by doubling the scale of the diagram, the distance between the equipotential surfaces will everywhere be doubled, halving B everywhere, but quadrupling the area through which it flows, leaving the aggregate flux twice as great.

It is worth passing attention to notice the distribution of flux in a case where there is no system of potential, — the interior of a current-conveying conductor, — as already mentioned. Let R be the radius of a circular wire over whose cross-section A O B, Fig. 13, the current is uniformly distributed. At the axis O, there is no flux, but from this point outwards the flux steadily increases. At any point P, distant r from O, the current in the external cylindric shell of radii R and r, produces no influence, and the intensity is that which would be produced at the surface of a wire of radius r having the same current density. This intensity from what we have seen in Chapter II would be

$$\frac{2c}{r}\left(\frac{r^2}{R^2}\right) \text{ or } \frac{2cr}{R^2}.$$

The flux takes place in circles all concentric with the axis of the wire. The M. M. F. in any circle of flux is $4\pi c\left(\frac{r^2}{R^2}\right)$, but this cannot be distributed potentially so that the gradient shall coincide with B.

MODERN AMERICAN TELEGRAPHIC APPARATUS—II.

BY

F. W. Jones

SINGLE TRANSMITTERS AND SOUNDERS.

To C. A. Nystrom, of Sweden, is accorded the credit of having invented the continuity-preserving key as early as 1855, and it was variously used in attempted duplex telegraph transmission by early experimenters, including Moses G. Farmer, who applied the principle to a polarized differential duplex system in 1858.

The continuity attachment in all cases had been attached directly to the key until 1868 when J. B. Stearns employed it probably for the first time combined with an ordinary sounder so that it could be independently operated by the key, permitting the operator sending to hear his own signals the same as when working a single Morse wire.

In 1872 the Western Union Telegraph Company introduced the Stearns duplex system very extensively on its wires and the Stearns sounder transmitter was used until 1873 when it was superseded by the pattern shown in Fig. 1, which notwithstanding its serious mechanical defects held almost universal sway until 1889 when the improved transmitter shown in Fig. 2 was adopted by the Postal Telegraph-Cable Company.

Refering to Fig. 1, the spring C is made of a thin piece of flat steel known as clock-spring attached rigidly to a rubber block mounted on the end of lever B and so bent that it makes electrical contact through platinum points with a hooked projection of the lever when the latter is released by the electromagnet, and with the battery post D, via contact C, when the lever is in its closed position, as shown in Fig. 1.

---

[1] Professor Perry: *Phil. Mag.*, Dec., 1891.

In practice this spring frequently gets bent or loses its normal elasticity or harbors a particle of dust or oxide, so that a very minute opening of the contact, or an imperfect vibratory contact results at the point X. The position of this defect is so obscured and the characteristics so similar to an opening in the battery or other part of the circuit that the average chief operator is baffled in a speedy location of the trouble.

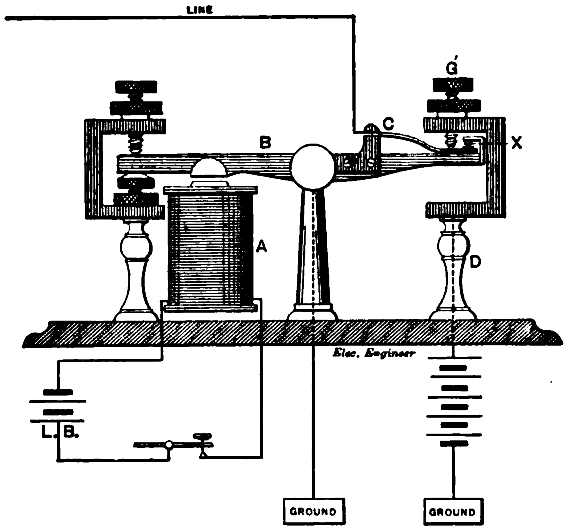


FIG. 1.

Various manufacturers differ in the size and quality of the steel and, as furnished, the spring C varies greatly in its tension; moreover it is non-adjustable and cannot be adapted to the inevitable variation of the battery current from L B in the electromagnet A that operates the lever B.

There is a tendency of a rebound between spring C and end of G', and it is very instructive to the electrician to use a telephone in testing the operation of transmitters as it will show how fallacious are the conclusions based upon the eye and theory in such matters.

This transmitter has yet another drawback in not possessing clear-sounding properties with ordinary local currents, as the lever is arrested in its downward stroke by the resistance of spring C at end of G' and there is an impairment of the sound which should be loud and clear for the benefit of the sending operator or attending chief operator. The difference in sound when C is removed is very marked.

In the apparatus shown in Fig. 2 the foregoing disadvantages have been almost entirely eliminated. Here lever B on its down stroke clears the supplemental lever C, relieving it of the vibration set up in B, and at the same time giving an unmuffled sound. The contacts at E and X can be regulated to be made with equal pressure by the lever at any workable strength of current in the electromagnet M.

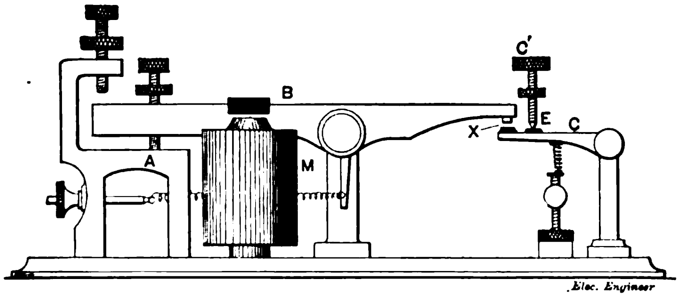

FIG. 2.—POSTAL TELEGRAPH-CABLE SOUNDER-TRANSMITTER.

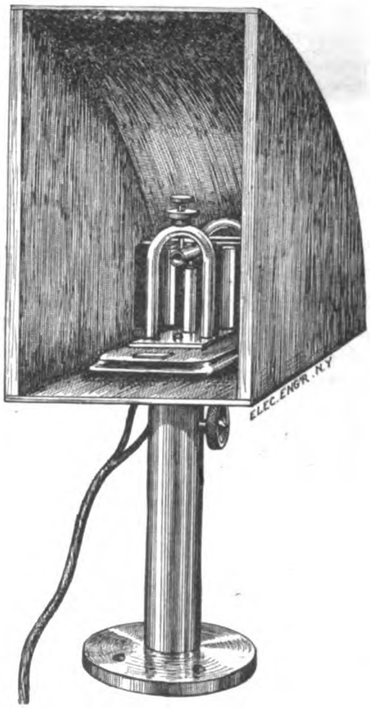
A peculiar feature of American telegraph systems is exemplified by the very large use during the past decade of sounders and transmitters having electromagnets of ridiculously small proportions, the prevailing size having bobbins about 1¼" long and 1" diameter, over all. The standard size of each bobbin adopted by the Postal Telegraph-Cable Company is 1½" long and 1¼" diameter (over all) in which coarser wire may be employed.

A comparison of the two magnets, each wound to 20 ohms with a continuous current of 125 milliamperes shows the 1¼" × 1" magnet to have an inductance of 191 millihenrys and a time constant of .0095 second. The 1½" × 1¼" magnet has an inductance of 130 millihenrys and a time constant of .0065 second with the armatures 4 mils from the cores. The latter magnet has nearly twice the pull at the armature with a given battery, and its larger time constant is not serious enough to be noticeable.



ELEC. ENGR. N.Y.

FIG. 3.—THE POSTAL TELEGRAPH RESONATOR.

The adoption of typewriters by the Postal Telegraph-Cable Company for the reception of its messages introduced a disturbing sound from the clatter of the keys of the machine. This makes it necessary to obtain distinct and loud sounds from local instruments, and enlarging the bobbin contributes to this and without additional expenditure of energy.

Fig. 3 is a resonator I have recently introduced similar to those used in the postal telegraph service in England but smaller and better adapted to our service. It is placed on the table to the left and near the receiving operator and the sounder is placed inside and connected by a flexible cord which passes through a hole in the bottom near the upright standard. The resonator is turned so that the volume of sound is thrown in the direction of the receiving operator who (on a quad table) sits on the left of the sending operator. Thus both are enabled to hear while the sound is screened from all other directions.

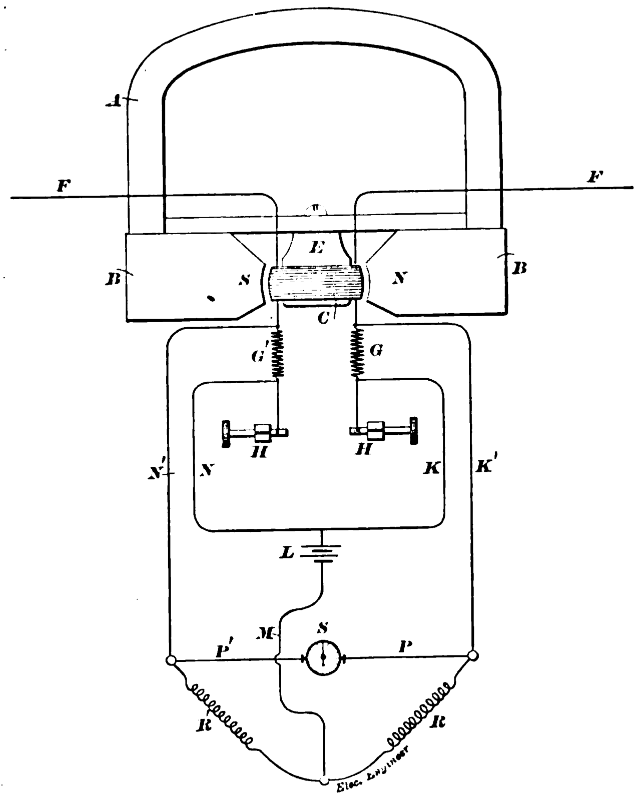
A STRANGE case of one-way conduction, says *Industries*, is mentioned by M. E. Branly. Hot gas conducts—as is well known—but with one electrode cold it conducts best when that electrode is negative. This phenomenon is probably intimately connected with that recently discussed by Dr. Fleming in his Royal Institution paper on the phenomena of discharges in incandescent lamps.

THE CUTTRISS CARBON RELAY FOR SUBMARINE CABLES.

BY

Chas Cuttriss

Until within a comparatively recent period telegraphy was the most important branch of electrical engineering, but of late years developments in electric lighting, power and traction have been so marvelous and we have become so accustomed to calculate and think of volts and amperes by the thousands and tens of thousands that the mind has to exert itself somewhat to realize that instruments using only the hundred-thousandth of an ampere for a maximum current and a millionth of an ampere for a minimum current, are in daily use, and that by means of them we annihilate time and link together the Old and New Worlds.



The Cuttriss Carbon Submarine Cable Relay.

Nevertheless, this is a fact, and by means of these minute currents communication at the rate of 25 words per minute is steadily maintained over the Atlantic cables for hours at a time. That this may be done it has become necessary to abandon to a great extent the old system of manual transmission and to adopt an automatic mechanical transmitter, so that we can now insure the same perfection as regards the shape of the signals and the required spaces, at the end of a twelve or twenty-four hours' run as we had at the start.

A few years ago the public were content to send a message to London and get an answer within an hour; now they can get it in a minute or two; but still the cry is for quicker communication. As the adoption of the automatic system of transmission has increased the carrying capacity and speed of long cables to the utmost we can only hope for still more rapid communication between terminal stations by saving the time now lost in the necessary retransmission of messages at intermediate stations. This, of course, can be done by interposing a relay which shall automatically repeat into the second cable the signals which come over the first one. As all signals over a submarine cable of any length are of an undulatory character, it becomes necessary that this relay should repeat these undulations into a local circuit as faithfully as a telephonic receiver reproduces the undulations of the diaphragm of its transmitter.

After many failures to attain this end during the last ten years, the instrument shown diagrammatically in the accompanying engraving has been invented by the writer. By its means the connecting in series of a number of short cables of about 800 to 1,000 miles in length or the connecting of a short cable to a long one is perfectly feasible. Up to the present time a relay known as the Allen & Brown has been practically the only one that would work Morse over cables 500 miles long, and with cables of this length the utmost delicacy of adjustment was necessary to obtain satisfactory signals.

Heretofore there has been no instrument which would repeat recorder signals into a local circuit, thereby making it possible to have several offices in a city working directly on to a through cable after the manner in which Morse instruments at various offices work onto one trunk line. In the spring of 1889 I first obtained reliable recorder signals in a local circuit by means of a repeating relay in circuit with the Commercial Cable Co.'s Canso-New York cable, the copper resistance of which is 13,600 ohms, with an electrostatic capacity of 233 microfarads and a length of 855 knots; the cable is duplexed, and a battery power of 30 volts is used for signaling.

The relay was crude and consisted of a coil of peculiar shape, which carried two small carbon discs and which moved in a magnetic field; this coil was placed in the cable circuit. Opposite to the two discs were carbon points, which were connected in a local circuit to the receiving instrument, consisting of two ordinary 8-inch horseshoe magnets, between the poles of which a small coil carrying the syphon was pivoted, the syphon dragging over the surface of the paper.

When the operator at the distant station sent signals, to my surprise they were recorded on the receiving instrument perfect in shape and character, and subsequent measurements showed that the power in the local circuit was upwards of fifty times as great as the initial cable current. Since then I have experimented in every way to find the best form of contact points, but have finally rejected points of any shape as the adjustments had to be too delicate and the points showed a great tendency to stick and burn.

I then turned my attention to making helices of carbon and found that by substituting them for the adjustable points all the troubles incident to sticking and burning were eliminated, and that they gave a variable circuit that is entirely under the control of the movable coil. The relay now repeats most minutely all the undulations of the cable currents.

The strength of the currents in the local circuit can be augmented to such a degree that the local instrument requires no delicate parts and can be adjusted by the operator instead of requiring the services of a skilled mechanician.

As will be seen, N S are the poles of a permanent magnet; E is an iron core situated between them so as to concentrate the lines of magnetic force into two fields in which a coil C is pivoted at the top and bottom. Thus far the instrument is a copy of the syphon recorder, but instead of using metal springs, weights or analogous devices, to bring the coil back to zero after it has been deflected by a signal, I have substituted the carbon helices G G', connected to the coil by fibres or otherwise, and it will be readily seen that any deflection of the coil must open one spiral and close the other.

Normally the circuits, M, R', R, K', N', G, G', N, K and L are so balanced that there is no difference of potential at the extremities of the wires P and P'; consequently the local instrument S is unaffected. Should, however, a signal be sent through the coil c it will tend to close one of the carbon spirals and open the other, thus throwing the local circuit out of balance and energizing the local instrument s to a degree corresponding with the movements of the coil; the amount of the energy thus developed follows the laws of the Wheatstone bridge.

By varying the resistances in the local circuit and the strength of the battery we can obtain any desired power in the local instrument, and, if necessary, a number of them can be placed in various offices in a city by means of the circuit P P′.

It was while experimenting with the instrument and observing the perfect manner in which the weak cable signals were reproduced by these carbon helices, that I was led to try them as a telephonic transmitter and was not surprised to find their action all that could be desired. The results obtained have already been described in these columns by the writer.[1]

Legal Notes.

FINAL HEARING ON EDISON'S "FEEDER AND MAIN" PATENT FOR ELECTRICAL DISTRIBUTION.—II.

THE DEFENDANT'S CASE.

The complainant has sought, with much persistence, to introduce considerations which seem to have no proper bearing upon the interpretation of the patent, but serve merely to obscure the real issue, hence it will be useful to state at the outset the defendant's view as to the real nature of the alleged invention of the patent in suit. The particular subject-matter with which the patent purports to deal is electric pressure or tension, and the alleged invention purports to provide a remedy for the drop or fall in electric pressure due to the resistance of the main conductors. It is practically impossible to formulate any intelligent definition of electric pressure or tension without recourse to fluid analogies, and such analogies are serviceable, not alone as illustrations, but because it is a fact generally accepted among scientific men, that so far as concerns the general laws of flow and distribution, electricity behaves in all substantial respects as if it were a fluid. The patent states that where the main conductors of a system of electrical distribution extend to a great distance from the central station and supply a large number of transmitting devices, there is inevitably a difference in tension between the various parts of the circuit due to the resistance of the main conductors. The specification says:

> "This may be partially remedied by making the conductors very large near or at the station, gradually decreasing their size or conducting capacity; but such plan only lessens slightly the ratio of fall."

The latter part of this statement is not true as a matter of fact. The difficulty could be entirely remedied, as admitted by complainant's expert, Prof. Chandler, by increasing sufficiently the size of the conductors. The patentee then describes the remedy he proposes for the difficulty by the use of special feeding conductors "having no translating devices connected therewith," and further on describes the manner in which the feeding conductors and the main conductors of the consumption circuit are to be proportioned, or, in other words, how their relative sizes are to be adjusted. The specification states in substance that the circuit consists of two essential parts, the "feeding conductors" and the "main conductors of the consumption circuit." It is obvious that by reason of the mere form of the circuit, irrespective of its proportions, any drop in pressure on the feeding part of the circuit cannot affect the relative pressure in different parts of the consumption circuit, or the relative candle power of lamps connected with that circuit at different points. The specification says that the main conductors "should be so proportioned that the drop upon them shall not exceed a definite small limit." No instructions are given here or elsewhere in the specification, as to how this result is to be secured. No instructions are given as to any definite proportions, either of the main or the feeding circuit, nor what the "definite small limits" is, nor what variation in candle power is permissible. Taking all the statements together, they merely direct the constructor to proportion the consumption mains (if he knows how to do it) in such a way as to bring the variations in pressure within such limits as he finds necessary or desirable, and to proportion the feeding conductors (if he knows how to do it) in such a way as to incur any drop in pressure along that he finds desirable.

Each claim of the patent is in terms for a single circuit, and the gist of each claim consists in combining such single circuit, feeding conductors for conveying electricity from the generator to the place where it is to be distributed, with a consumption circuit for distributing the electricity so conveyed to the various points to be so supplied.

Complainant's experts have made a strenuous attempt to show that there are certain broad limitations which sharply distinguish the circuit covered by these claims from anything which preceded it in the art. Professor Chandler contends that central station regulation is an essential part of the system claimed. Sir William Thomson insists that central system regulation is an important and indeed an essential part of the system he is discussing. They say that the circuit covered by the claims is a "comprehensive system" involving the use of "large numbers of incandescent lamps," with conductors extending "great distances" and covering "large areas" and involving the use of a "central station." But when asked to define these terms they are wholly unable to do so. The plant in the Dundee mill, referred to by Sir William Thomson as one of the best embodiments known to him of the feeder-and-main system, comprises 800 lights used for lighting a single building. When asked to define what he means by "a large number" of lights the best definition he can give is: "I should think a good many hundreds—one hundred scattered over a considerable distance." All these vague limitations elude analysis, and will not bear examination. They are part of a studied attempt to lend fictitious dignity to this alleged invention, and to conceal its true character as a simple engineering expedient, by attributing to it the merit attaching to all the work that Mr. Edison and others have done in electric distribution, and to convey the impression that it is something large, complicated, and difficult of comprehension, requiring inventive genius of a high order to accomplish. Defendant does not, (nor apparently does complainant) attribute importance to the limitation of the third claim, that the feeding conductors are to be connected to the centre of the main, as conferring patentability, although in the original application this was made the principal feature of the invention. The adjustment of relative size of the different parts of the circuit consists merely in making the feeding conductors of any size desired, and in making the consumption conductors sufficiently large to keep variations in pressure within such limits as may be desirable. The real issue, so far as patentability is concerned, is whether this circuit was new with Mr. Edison, or required invention in view of the prior state of the art. The *form* of the circuit was one which must necessarily exist in all cases where the lamps are at a considerable distance from the generator. Such cases frequently arise in practice and it could hardly have involved invention to arrange the circuit in the only way it possibly could be arranged. No specific proportion of feeding conductors is called for by either of the claims, and in any event it could require no invention to use small enough conductors to incur any loss of pressure that for any reason might be desirable. The only remaining question is, whether it would require invention to make the distributing conductors large enough to distribute the current with proper equality of pressure, and this, by the admission of complainant's witnesses, is the only issue in the case, so far as patentability is concerned. Mr. Jenks, in his New York Electrical Society paper, says:

> "The feeder principle of distribution * * * * is entirely original with Mr. Edison, the methods of the gas companies, which were closely followed so far as they were adaptable to the government of the more potent agent which we utilized, did not at the time of the application for the feeder patents include any analogous means of equalizing pressure."

This statement carries by necessary implication the conclusion, that *if* the methods of the gas companies had included any analogous means of equalizing pressure (as it has been shown that they did) Mr. Edison would have adopted them if he had known of them, and Mr. Jenks would not have considered the feeder principle original with Mr. Edison. Mr. Edison himself, in numerous published statements has insisted upon the analogy between his system and the gas and water systems. As a matter of fact, the methods of both the gas companies and the water companies did include strictly analogous and, in fact, identical means of equalizing pressure, and this is true to such an extent, especially of gas distribution, that the descriptions of prior gas systems in the testimony of defendant's witnesses, and in prior publications in evidence, would, by mere translation of the gas terms into the corresponding electrical terms, constitute a much better specification than that of the patent in suit, of the system of distribution covered by its claims.

It is conceded that the alleged invention of the patent in suit is applicable to the multiple arc system of distribution only, and has nothing to do with the series system; it is not, however, claimed that the multiple-arc system of distribution was invented by Mr. Edison. Nor was he the first to discover that the resistance of a conductor carrying an electric current produces a drop in the pressure or tension of the current. The effect of changes in the size and length of the conductor, and of changes in the strength of the current traversing it, upon the fall of pressure, were well understood by electricians long prior to 1880, and formulæ had been worked out for calculating the proportions to be given to a conductor for securing a definite fall in pressure with a given current. It has been abundantly proven to have been a part of the common knowledge of the art, that for economically transmitting large volumes of electric energy to long distances, conductors should be used of considerably less size than would be required for maintaining an approximately equal pressure along the entire line of the conductor, and indeed this is admitted by Professor Chandler.

---

[1] The Electrical Engineer, Dec. 16, 1891.

The claims in suit are anticipated by prior publications an uses relating to electroplating and electrotyping, in which t multiple-arc system of distribution was employed. The necessity for equalization of pressure in these applications is fully as great as in electric lighting, as has been recognized for many years. Long prior to the date of Edison's alleged invention, the method of equalizing pressure described in his patent has been utilized, viz., making the distributing parts of the circuit of sufficiently thick conductors to avoid resistance, producing inadmissible differences in tension, and using conductors to transmit the circuit from the generator to the distributing conductors of any desirable size, without reference to the fall of pressure in them. The criticisms of complainant's experts as to the size of the apparatus, the length of the circuits, and the pressure of the current, are wholly immaterial to the question at issue, since it could manifestly involve no invention whatever to apply upon a large scale a principle which had been recognized and applied upon a small scale.

The British patent to Werdermann and the Werdermann article in the *Telegraphic Journal* describes a peculiar form of multiple-arc circuit which has become known in the art as the "reversed parallel" circuit. So far as concerns the *form* of circuit of the patent in suit, it is shown in these publications, since no fall of pressure in the feeding circuit can affect the relative candle power of the lamps connected with the other part. It is apparent that Werdermann's system was intended for distribution on a large scale and over considerable distances. The desirability of uniformity of candle-power is also recognized by him. Complainant's experts say that the vital difference between this system and that of the patent in suit is, that the former does not describe central station regulation. This is immaterial. The patent in suit does not describe central station regulation, and such regulation forms no part of its claims. Another criticism is that Werdermann describes an arc lamp, and proposes to use a current of low tension which would be unsuitable for wide distribution. This also seems quite immaterial. The gist of the invention of the patent in suit (if there is any invention) consists in the arrangement and proportioning of the circuit for securing uniformity of pressure, and this is not dependent on the kind of lamp or the tension of the lamp employed. Prof. Chandler's contention that it would require invention to use a lamp of higher resistance, and a current of higher tension for operating it in the Werdermann circuit, is of interest rather as showing to what shifts complainant's experts have been driven in an attempt to sustain a position legally untenable, than as requiring serious attention. Prof. Chandler thinks it would have required invention to use the Lane-Fox lamp in the Werdermann circuit, with a current of the tension specified by Lane-Fox for operating it. This, it is submitted, presupposes altogether too dense an ignorance, on the part of every one except Mr. Edison, of the commonest principles of electrical engineering.

There is no doubt that the French patent of Khotinsky describes the *form* of the circuit of the patent in suit. There is one part of the circuit, the two main conductors, to which all the lamps are connected, and there is another and distinct part of the circuit, the two wires connecting the magneto-electric machine to the main conductors, and to which no lamps are connected. It is specially to be noted that it describes the connection of the feeders to the centre of the main conductors, specified in claim 3 of the patent in suit. The only real issue in regard to Khotinsky is narrowed down to the point whether in using his form of circuit, under circumstances sure to arise in practice, it would require invention to make the main conductors of the lamp circuit large enough to be practically useful.

The Lane-Fox patents and publications are important, as showing an intelligent appreciation of the fact that fall of pressure was a difficulty which would be encountered in a multiple-arc system of distribution on any extended scale; that the difficulty was due to the same causes of resistance to flow in the conduits, which produced the same difficulty in gas distribution, and that therefore it could be dealt with in the same way in electrical distribution as in gas distribution. As a general remedy, applicable so far as practicable, he adopted from gas distribution the proper proportioning of the distributing mains, making them large enough to avoid any harmful pressure. Then by reason of the extent of the system, it became impracticable to make the mains large enough to entirely obviate the difficulty; he therefore adopted one of the methods used in gas distribution, that of automatic pressure-regulators. He does not describe the other method—equally well known in gas distribution—independent feeding mains with pressure regulators at the works; possibly because he was ignorant of it, but probably because he thought it was unnecessary. Lane-Fox's selection from gas methods turned out not to be a judicious one; the other one, that of independent mains, which Edison selected and described in the patent in suit, is better adapted to the requirements for electrical distribution, but both will accomplish the result, and both are borrowed bodily from gas distribution.

The Sawyer and Man patent of 1878 describes a multiple-arc circuit, identical in form with Fig. 2 of the patent in suit. The Sawyer and Man patent does not describe proportioning of the parts of the circuit, and hence the same considerations apply to this patent, in this regard, as to the Werdermann and Khotinsky patents.

That the elements of the combination of the patent in suit were all old, follows necessarily and as a legal consequence from the mere statement that they are elements of a combination, as has been shown by abundant authority. Moreover, the evidence shows in fact, that these elements were old and well known in the prior state of the art. This proposition remains entirely undisputed, except as to a consumption circuit, properly proportioned, forming one of the elements of each claim. This is admitted by complainant's expert, Sir William Thomson, to be old, or at all events to be such a construction as would naturally have suggested itself to a person skilled in the art; complainant's other expert, Prof. Chandler, made the same admission on cross-examination, and his subsequent attempt to take a different position is a flat contradiction of his previous testimony and is in any event wholly illogical. Such a consumption circuit was in fact described in the prior patent of Lane-Fox; was well known in electroplating, and would not in any event have involved any invention, but only the exercise of mere mechanical skill and judgment, in view of its well-known application in the strictly analogous arts of gas and water distribution, and the common recognition among electricians of the strict analogy between multiple-arc electric distribution and gas and water distribution. Furthermore, the proportioning of the consumption mains in the claims in suit was not described at all in the original application for the patent, and if it was not well known in the art, then the patent is for a different invention from that described in the orignal application, and therefore void. This is the logical result of the position Prof. Chandler endeavors to take in regard to the Lane-Fox patent. There is no escape from this dilemma: Either the claims of the patent cover an invention not described in the original specification, or the fourth element of the alleged combination, viz., a properly proportioned consumption or service circuit, was not in itself new at the date of the application, or of Edison's alleged invention, but had been described in the Lane-Fox patents and publications, or was otherwise known to persons skilled in the art.

It is further contended by defendant that there is no patentable novelty in the combination claimed. It is established by the evidence of complainant's own experts, that the combination covered by the claims of the patent in suit did not involve the exercise of invention, but merely of engineering or mechanical skill, in view of the state of the art at and prior to the date of Edison's alleged invention. The gist of the alleged invention consists in nothing more than the use of transmitting conductors, of any size that may be desirable, for construction or otherwise, to transmit the current from the generator to the place where it is to be distributed, and distributing conductors made large enough to distribute the current without causing by their resistance inadmissible differences of pressure. Complainant's experts admit that the use of such transmitting conductors was well known in the art, and that it would not have involved invention, but the merest engineering skill to use such transmitting conductors for supplying current at a distance for any purpose whatever. The only question left, therefore, is whether it would have involved invention to make the distributing conductors large enough under such circumstances. Sir William Thomson admits that such construction would have naturally suggested itself to a constructor at that time. Prof. Chandler admitted the same thing on cross-examination, but retracted it on redirect. As a matter of fact, the proofs show that such construction of the distributing conductors was described by Lane-Fox in his patent of 1878, and had been used largely in electroplating. The prior patents of Werdermann and Khotinsky undoubtedly described the *form* of circuit covered by the claims in suit, and the *proportioning* of the circuit in the manner set forth in the patent was a matter not requiring invention, but only the exercise of the merest engineering and mechanical skill and judgment at the date of Edison's alleged invention. If these claims are valid they preclude the public from using the forms of circuits described by Werdermann and Khotinsky, in cases frequently arising in practice, such as the lighting of a building from a generator some little distance away, in the manner which would necessarily be adopted by any engineer, unless he ignored the commonest expedients known in the art at that date.

The prior publications and uses relating to gas and water distribution constitute a complete anticipation of the claims of the patent in suit. All the points of difference between gas systems and electrical systems, insisted upon by complainant's experts are mere differences in detail, not in any way affecting the general principles on which the claims depend, and the general principles contained in both cases, especially so far as relates to the specific matters dealt with by the patent, are identical.

The system of distribution covered by the claims in suit is not a legitimate combination within the meaning of the patent law, but a mere aggregation, and therefore not patentable subject-matter. Two distinct functions are involved in the system of circuits described in the patent: Transmission of the electricity from its source to the locality where it is to be utilized, and distribution of the electricity among the devices there to be supplied. The system is therefore one of transmission *and* distribution; not one of distribution alone. The function of transmission is performed solely by the feeding circuit; that of distribution solely by the transmitting circuit. Each part of the circuit works after its kind, without reference to what occurs in the other part. This independence of function is recognized and even emphasized in the specification. There is no co-ordination of functions, and no unitary result, but a mere aggregation of functions and aggregation of results. This is not a mere technical point of law, but goes to the merits of the case. It is another way of stating that the various elements of the alleged combination are used to perform their recognized functions; with such results as would naturally be expected, because they were the ordinary results of the action of the parts. Such an aggregation is not patentable. It was doubtless to avoid this conclusion that complainant made such strenuous efforts to inject central station regulation into the patent, as an essential element of the combination, to furnish some connecting link giving apparent co-ordinate action to the parts, but the patent furnishes no warrant for this, and in any event it would not materially affect the question.

To create a further presumption of patentability complainant has tried to prove that the alleged invention supplied a long felt want, and was immediately recognized as a very important contribution to the art, but all the testimony of complainant's witnesses on this point is a studied attempt to confuse the *specific* problem of equalization of pressure, with which the patent purports to deal, with the *general* problem of producing a comprehensive system, capable of supplying the electric light for general illumination. It is a fact that this general problem was a very difficult one and was universally so considered, but it is not true that the specific problem of the patent in suit was regarded by any one prior to Edison's alleged invention except perhaps by himself and his associates, as involving any invention whatever. The testimony of complainant's witnesses is, that no experiment was required for making the alleged invention, but on the contrary Edison proceeded, without making any experiments whatever, to embody the system of circuits in a large and extremely costly plant in New York City. This would indicate that so far as he was concerned, the applicability of the scheme to an incandescent lighting system was quite obvious, without experiment, as soon as the occasion arose for using it.

The history of the application of the patent in suit, as revealed by the proceedings in the Patent Office, shows that an amendment of a radical nature was made more than two years after the application was filed; made by the attorney without any oath from Mr. Edison or any one else; that the element containing the very gist of the claim, viz., a properly proportioned consumption circuit, was not described at all in the original specification, but appeared for the first time in an amendment filed by Mr. Edison's attorney. In the original application the principal features of the invention were: 1. Having no lamps on the feeding conductors; 2. Feeding conductors to tap the lamps of these conductors at their centres; 3. Lamp-circuit conductors to taper from the centre to the ends; 4. Lamps placed on circuits derived from lamp centres only. By eliminating the central connection of the feeders, not only was the scope of the invention materially broadened, but the very corner-stone of the invention, so far as concerns equalization of pressure in the lamp circuit, was removed bodily. The tapering of the lamp-circuit conductors, an essential part of the original statement of the invention, was also eliminated in the amended specification. The changes in the specification were necessarily radical, because the claims in suit could not have been supported by anything found in the original specification. Mr. Brevoort undertakes to say that "the file-wrapper all through describes and explains the invention set-forth in the first three claims in the patent." Complainant's case on this point is perhaps not helped by this opinion under oath on a question of law, and it may be remarked in passing, that the particular expert selected for this purpose is one who has had no practical experience in electric lighting and who is least acquainted of all complainant's experts with the art. On his own showing he has made no examination of the literature of the subject and has no familiarity with it, and hence has no special competence to instruct the court even upon the technical points involved. None of the other experts have undertaken to verify this proposition of law. The amendment in fact constituted a description of a new invention, not described at all in the original application, which is made a constituent and essential ingredient in each of the claims in suit. There is therefore, a fatal variance between the present claims and the original application, and the claims are for that reason void.

Futhermore, prior to the filing of the real application of the patent in suit, viz., the amendment filed August 1882, Edison took out another patent in which the invention now claimed is described but not claimed. By this description in a prior patent, the patentee and his assignee of both patents, the complainant, is estopped in asserting any novelty for it in this patent, hence the claims in this patent are void for this reason also.

The evidence on the issue of infringement is very conflicting. The complainant has not only failed to sustain the burden of proof, but the preponderance of evidence shows a construction of the circuits of defendant's plant which would not, upon any admissible interpretation of the claims be covered by them.

It is respectfully submitted that the bill should be dismissed with costs.

Letters to the Editor.

THE LONG-DISTANCE SYSTEM.

REFERRING to Mr. F. W. Jones's letter in THE ELECTRICAL ENGINEER of May 18, it is a fact that on various occasions talking has been carried on in this country over lines whose value expressed in KR considerably exceeded 10,000. According to the formulæ, we are told that when the value of the loop exceeds 10,000, or for a copper metallic circuit 40,000, the speaking "commences to become difficult." It may go on becoming difficult for a considerable addition of KR without becoming altogether impossible—when special experiments are made by experts. We heard the other night at the Institute dinner from Mr. Lockwood that experimental success is something quite different from commercial success, and it is pretty well known that telephone experts can talk over lines that non-experts can do nothing with. I do not think I can be held personally responsible for the success of any experiments undertaken by the Long-Distance Telephone Company; I merely recorded that such experiments had been made with a certain amount of experimental success. Doubtless the commercial success will follow later.

It is difficult to please Mr. Jones. First, he has his little fling at the length of the article, and then he complains that it was not longer and did not contain tables of sags and stresses, diameters of poles and other text-book information. He might have pointed out other omissions of a similar character, but your columns could scarcely be spared for a technical treatise on telephony; the article was intended merely as a general description of the Long-Distance Telephone system. To make it include the specifications that Mr. Jones asks for, would be to start out on different lines altogether and write a book instead of an article. If Mr. Jones really needs the information, the engineer's office of the Long-Distance Company is the proper place to apply to—it is all there. As to the splice, it is mentioned on page 448 near the bottom of the second column.

Regarding what Mr. Jones says about the "unwarranted belittlement of neighbors," I do not think he makes out much of a case. I stated very distinctly that the Long-Distance lines had had their breakdowns after extraordinary storms; I did not refer to the fact that telephone poles had been laid low in New York City by the snowstorm in January of last year, because that had nothing to do with the case. The fact remains, however, that there is no other overhead construction in this country to be compared with the Long-Distance lines, and further, that on many occasions when all telegraph service is interrupted by stormy weather the telephone service is maintained without interruption or delay.

HERBERT LAWS WEBB.

NEW YORK, May 21, 1892.

Society and Club Notes.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

THE annual meeting of the Institute to receive reports and for the election of officers was held at the headquarters, 12 West 31st, St. New York City, on May 17, 1892, at 4 p. m. Vice-President T. D. Lockwood in the chair. A report of the year's work ending April 30, was made by Secretary R. W. Pope. It showed a total membership of 615, namely, 3 honorary, 179 active and 433 associate. The net gain over 1890–1 was 74 members. The report of Treasurer G. M. Phelps showed a total of receipts of $6,717.48, and that the total balance in the hands of secretary and treasurer was $271.09. To this surplus may be added a special deposit of $850 now standing to the credit of building fund and drawing 2 per cent. interest. The total balance on hand to the credit of the Institute May 1, was $1,095.53. These reports were accepted.

The chairman announced that the Council that afternoon had elected to honorary membership, Lord Kelvin, Werner Siemens and Cyrus W. Field.

The officers whose names are printed in italic were then elected, those holding over being printed in roman: *President, Frank*

Julian Sprague; vice-presidents, A. E. Kennelly, Nikola Tesla, Oscar T. Crosby, T. D. Lockwood, Carl Hering, W. J. Hammer; *managers, Charles Wirt, A. S. Hibbard, Dr. M. I. Pupin, C. P. Steinmetz*, J. C. Chamberlain, P. B. Delany, H. A. Foster, H. Ward Leonard, Dr. Louis Bell, H. L. Webb, Prof. A. G. Compton, J. Hamblet; *secretary, R. W. Pope*, re-elected; *treasurer, G. M. Phelps*, re-elected.

It was voted that a committee of the Institute to report at the Chicago meeting, be appointed by the president to recommend a revised plan of election of officers of the Institute, so as to enable the whole membership to participate in the choice.

President-elect Sprague on being escorted to the chair, said that he only expressed the unanimous feeling when he asked for a vote of thanks to Mr. Lockwood for the manner in which during the year he had practically discharged all the active duties of president, on behalf of Prof. Bell. The vote of thanks was carried, all the members rising.

Mr. Sprague then appointed as the committee on revised plan of election: Dr. F. B. Herzog, chairman; Messrs. F. R. Upton and T. C. Martin.

At 6:30 p. m. about 70 members of the Institute sat down to dinner at the well-known "Arena" restaurant adjoining, and a most enjoyable evening was spent in an informal manner. Mr. Sprague presided, with Mr. Lockwood and Prof. Geo. Forbes on his right and left. During the evening speeches were made by Messrs. Sprague, Lockwood, Prof. Forbes, Mr. Oberlin Smith, past president of the American Society of Mechanical Engineers; Dr. Charles E Emery, F. L. Pope, O. T. Crosby, T. C. Martin and Dr. Louis Duncan. There is no question that the success of the dinner will make it an annual affair.

THE CANADIAN ELECTRICAL ASSOCIATION.

THE first annual meeting of this Association will be held in the city of Hamilton on Tuesday, Wednesday and Thursday, the 14th, 15th and 16th of June next. Arrangements have been completed for papers on the following subjects, and others will be announced in the official program:

"Financial Aspects of Electric Lighting in Canada," by Mr. S. J. Parker, of Owen Sound; "Long-Distance Telephony," with illustrations, by Mr. H. Neilson, of Toronto; "Safe Wiring for Electric Installations," by Mr. A. B. Smith, of Toronto; "Line Construction," by Mr. T. H. Wadland, of Hamilton; "Central Stations," by Mr. D. Thomson, of Hamilton; "Carbons," by Mr. H. O. Fisk, of Peterboro; "Steam and Electric Power," by Mr. J. J. Wright, of Toronto; "Multiple Switchboards," by Mr. J. A. Baylis, of Toronto.

The order of proceedings will be substantially as follows: Tuesday morning, executive meeting; afternoon, formal opening of the convention by the mayor and others. In the evening the members will visit the station of the Hamilton Electric Light and Power Co.

Wednesday morning and afternoon, session of Association, followed by an excursion to Burlington Beach, via steamer, and banquet there in the evening.

Thursday morning and afternoon, session, followed by a drive about the city and mountain.

The headquarters of the Association will be at the Royal Hotel, but the meetings will be held in the Board of Trade Building.

Although there will be no formal exhibition, any one wishing to exhibit apparatus will be provided with facilities in the way of current, etc.

The prospects of this Association seem very bright. At the last meeting of the executive committee, on the 10th inst., forty new members were admitted, and a growing interest is being manifested in the Association by electricians throughout the Dominion.

Reduced railroad and hotel rates have been arranged for, respecting which a circular will be sent to members in a few days. Other information can be obtained on application to the secretary, Mr. C. H. Mortimer, Toronto.

Literature.

HOUSTON'S ELECTRICAL DICTIONARY.

AN advance copy of the second edition of a dictionary of electrical words, terms and phrases, by Prof. Edwin J. Houston, has just been received from the publishers, the W. J. Johntson Co., Limited, *Times* Building, New York City. The book bears very little resemblance to the first edition which was published in 1889, and which is now so familiar to electrical readers. It is practically a new book, as it has been entirely rewritten and revised. The book is an octavo and contains 562 double-column pages printed on heavy paper. The type used is such that the titles stand out most prominently on the page. The definitions are given in two styles of type, the larger being used for the definitions proper, while the descriptive matter of a more general nature is printed in a smaller face of type. The illustrations are 570 in number and cover a very wide range of electrical apparatus. Definitions are given under about 5,000 distinct titles and nearly as many more titles are entered for the sake of giving cross-references to other titles under which their definitions can be found. The price of the book is $5.

THE WEST END RAILWAY, OF BOSTON.

AN interesting and handsome volume, with many cuts, descriptive of the development of the West End Railway, of Boston, as an electric system, has been published by Louis P. Hager, of 12 Pearl street, Boston. It is bound in cloth and the price is $1.00. Postage free.

MR. L. W. SERRELL, M. E., has contributed to the May *Engineering Magazine* an interesting article on "Electric Street Railways as Investments." It has now been reprinted in pamphlet form, and makes a very timely piece of reading for all who are interested in the subject.

Reports of Companies.

WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY.

THE annual meeting of stockholders of the Westinghouse Company was held at Pittsburgh, Wednesday, May 18. In advance of the receipt of an official copy of the report, the following figures are taken from the Pittsburgh *Leader*. The reports presented by the officers—from January 1, 1891, to March 31, 1892—showed a reduction in the company's indebtedness as follows:

	Jan. 1, 1891.	Mar. 31, 1892.	Reduction.
Bills payable	$3,076,021.11	$461,962.17	$2,614,058.94
Accounts payable	622,469 51	266,973 19	355,496 32
U. S. E. L. Co. bonds	750,000.00	650,000.00	100,000.00
Sawyer-Man Co. mortgage	210,000.00	210,000.00	———
Scrip dividend	195,962.00	194,362.00	1,600.00
Other liabilities	844,179.54	———	841,179.54
Totals	$5,198,632.16	$1,783,297.36	$3,415,334.80

There was paid for interest during the period covered by the report $135,356.64, making a total payment on account of debts and interest of $3,550,691.44. Of this sum $2,875,000.00 was provided by the sale of preferred stock, the remainder being supplied from earnings and collections. The sales from January 1, 1891, to the date of the report, including those of leased companies were $3,468,900.50.

The treasurer's balance sheet is as follows:

ASSETS.

Cash in banks	$88,145.24
Bills receivable	224,238.72
Accounts receivable	1,247,427.50
Material in stock (at cost of labor and material)	509,548 82
Advances to leased companies	1,045,057.81
Stocks and bonds	4,008,163.09
Real estate and buildings	415,092.77
Machinery and tools	459,968.86
Miscellaneous	63,424.75
Charters, franchises, patents, etc	4,816,717.19
	$12,402,769.75

LIABILITIES.

Accounts payable		$258,956.88
Bills payable		455,462.17
Scrip dividend		194,362 00
Stock subscription		85,075.00
U. S. E. Ltg. Co. 6 per cent. 15-year bonds, $50,000 payable annually		650,000.00
Capital stock liabilities:		
Preferred stock, 72,384 shares	$3,619,253.00	
Assenting stock, 100,758 shares	5,027,916.00	
Common stock, 5,526 shares	276,300 00	
In treasury, 21,832 shares		
		8,933,469.00
Surplus		1,880,445.20
		$12,402,769.75

Mr. Westinghouse presided throughout the meeting. In his report he directed attention to the impetus given the business of the company since its reorganization; the orders taken during the months of March and April last aggregating $1,576,235. The general and selling expenses had been so reduced that the company would be able to produce and market apparatus at lower prices than those prevailing last year. Over 1,600 men were employed by the company and its facilities were adequate to supply monthly sales to the amount of $500,000.

The following board of directors was elected: Charles Francis Adams, Lemuel Bannister, August Belmont, A. M. Byers, Charles Fairchild, Marcellus Hartley, George W. Hebard, Henry B. Hyde, Brayton Ives, George Westinghouse, Jr.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED MAY 10, 1892.

Alarms and Signals :—

Electric Indicator, J. W. Gibboney, 474,523. Filed Dec. 10, 1891.

Has for its object to reduce the number of circuits usually employed in electric signaling system.

Locking Device for Switch and Signal Operating Mechanism, T. H. Paternall 474,528. Filed Jan. 2, 1892.

Has for its object to prevent the possibility of changing a switch in a railway track until the train has responded to the corresponding signal.

Thermostat, A. H. Brintnell, 474,542. Filed April 11, 1891.

Designed to be very rapidly actuated to produce various kinds of alarms in accordance with the corresponding degrees of heat.

Automatic Fire Alarm, M. Martin, 474,670. Filed Feb. 21, 1887.

Electric Heat Alarm, J. Meyer, 474,673. Filed Dec. 14, 1891.

An automatic electrically operated heat regulator and fire alarm.

Conductors, Conduits, and Insulators :—

Electric Conduit, A. Bruner, 474,468. Filed March 7, 1892.

A water-tight conduit consisting of a series of pipes laid in a bed of waterproof material.

Insulating Couplings, A. Anderson, 474,569. Filed March 21, 1892.

Consists of two conducting links interlocked but separated from one another by a body of insulating material.

Connection for Electric Conductors, C. W. Tobey, 474,584. Filed Jan. 28, 1891.

A metal clip bent about the conductors and having its face provided with a coating of solder.

Distribution :—

Electrical Switchboard, L. A. Fehr, 474,632. Filed Nov. 28, 1890.

A switch pivoted in the centre of a board and adapted to connect with any one of a number of pairs of contacts placed about the board.

Dynamos and Motors:—

Dynamo Electric Machine or Motor, C. D. Jenney, 474,388. Filed Jan. 8, 1891.

Employs a frame fitted to receive and support a field magnet, the latter being secured to the frame and consisting of plates of sheet metal stamped out in the desired form and fitted within the frame.

Electric Speed Regulator, J. W. Gibboney, 474,447. Filed Sept. 26, 1891.

Claim 1 follows:

The method of maintaining a practically constant speed in a motor mechanism consisting in loading it with an electric generator and varying the effective magnetic field of said generator by changes in speed of its moving conductor

Commutator Brush, R. Hirsch & H. Meminger, 474.600. Filed Dec. 11,1891.

A commutator brush composed of a mixture of refined clay, graphite, carbonized oil or sugar, and wax covered with a metallic coating.

Circuit Controller for Electric Motors, W. S. Andrews, 474,623. Filed May 27, 1891.

Claim 4 follows:

The combination of a switch arm, a contact spring or plate at one end thereof, a contact co-operating with said spring or plate and a contact spring or plate at the opposite end of the switch arm, the latter spring bearing on a contact at each end.

Dynamo-Electric Machine or Motor, J. D. F. Andrews, 474,624. Filed Jan. 18, 1892.

Employs an armature having a ring core and two or more pairs of field magnet poles, the armature coils surrounding the core and connected together and to the commutator.

Electric Machine, H. A. Wagner & F. Schwedtmann, 474,787. Filed May 15, 1891.

Comprises a cylindrical field magnet and cap pieces forming bearings at each end for the armature shaft and completely encasing the armature.

Galvanic and Thermo-Electric Batteries :—

Exciting Fluid for Galvanic Batteries, C. Lutcke, Jr., 474,454. Filed April 17, 1890.

A concentrated solution of one or more chlorides such as copper, iron or zinc in combination with nitrate of mercury.

Heating :—

Electrically Heated Vessel, W. Mitchell, 474,398. Filed Sept. 5, 1891.

Employs an inner receptacle and an outer shell with an electrical resistance in the space between them.

Electrical Heater, W. Mitchell, 474,797. Filed Dec. 14, 1891.

Claim 1 follows:

In combination with tubular electric heater having a spider within it, a stand connected detachably to the said spider.

Lamps and Appurtenances :—

Electric Lamp Socket, W. D. Kurz & H. Amundson, 474,667. Filed Sept. 26, 1891.

A system of out-of-door decorative lighting using bare conductors.

Miscellaneous :—

Lightning Arrester, M. Dickerson, 474,469. Filed March 14 1892.

Invention consists in interposing between the discharge points a non-conducting liquid.

Ore Conveying Apparatus, T. A. Edison, 474,592. Filed Oct. 1, 1891.

Electric Wind Vane Indicator, H. J. Haight, 474,735. Filed Oct. 30, 1891.

Telethermometer, F. J. Dibble, 474,771. Filed Jan. 24, 1889.

Railways and Appliances :—

Electric Railway, Charles H. Baker, 474,355. Filed Oct. 30, 1891.

An elevated electric railway having a conduit secured to the ties between the rails.

Trolley-Wire Support, O. F. Evans, 474,375. Filed Jan. 24, 1891.

Employs the electric conducting wire as a support for the trolley wire.

Truck for Electrically Propelled Vehicles, L. Pfinget, 474,403. Filed Oct. 6, 1891.

Employs a counter-balancing device whereby a single motor may be placed at any convenient point upon a truck.

Cleaning Brush for Electric Railways, R. M. Hunter, 474,472. Filed Feb. 8, 1889.

A brush carried by a car operated by a conduit system; the brush being fitted into the conduit and carrying before it any accumulation of dirt, etc.

Trolley for Electric Railways, C. E. Friel, 474.552. Filed March 19, 1892.

Has for its object to prevent the trolley wheel from leaving the conductor at a curve or clamping on passing any irregularity in the wire.

Switches and Cut-Outs :—

Electric Snap Switch, G. K. Hutchins, 474,478. Filed Dec. 26, 1889.

Employs a base having two opposite non-conducting walls, two pairs of terminal conducting plates, a shaft centrally pivoted in the compartment thus formed, two pivoted circuit closing brushes and a separate spring acting on each brush.

Electric Switch, C. A. P. Willing and J. C. Violet, 474,541. Filed May 26, 1891.

A switch so designed that, on the closing lever being actuated, potential energy is first stored up, which, on the release of an arresting device, is transformed into kenetic energy, thus causing an instantaneous opening and closing of the circuits.

Telegraphs :—

Automatic Repeater, R. Watkins, 474,706. Filed Feb. 2, 1892.

A repeater placed in the secondary circuit and adapted to be operated from the main circuit by means of the reciprocating armature of the instrument.

PROF. HOUSTON TO LECTURE IN BROOKLYN.

PROF. E. J. HOUSTON, of Philadelphia, has consented to lecture before the Electrical Section of the Brooklyn Institute, on Wednesday, June 1, at the Young Mens' Christian Association, 502 Fulton street, Brooklyn. His subject will be, "Electricity One Hundred Years Ago and To-Day." Prof. Houston is a most interesting and instructive lecturer, and will be heard by a very large audience.

WESTERN NOTES.

THE CENTRAL ELECTRIC COMPANY report that they have secured the order through the Brush Electric Company for 82 miles Acme lead Okonite cable for the South Park commissioners of Chicago, the wire to be used in carrying current for the lighting of the boulevards to the World's Fair Grounds; Okonite being selected because of its high quality, and being able to conform to the stringent guarantees required.

MR. EUGENE A. ERICH, the Western agent of the Waddell-Entz Electric Co. has removed his offices from the Rookery to suite 1437-1438 Unity Building on Dearborn street, Chicago. The offices overlook the lake and will be handsomely fitted up, and several of the Waddell-Entz dynamos and motors swill be placed on exhibition.

L. K. COMSTOCK and W. D. BALL, both well-known consulting and contracting electrical engineers of Chicago, who have occupied an office together at No. 427 Rookery for some time past have removed to larger and handsomer quarters at room 419 Monadnock Building, where they will be glad to receive a call from their many friends.

THE BRUSH ELECTRIC CO. have removed their Chicago offices from 225 Dearborn street to the large and beautiful office building, the "Monadnock," corner of Dearborn and Jackson streets, where they have secured a suite of seven rooms extending across the entire front of the building on the post office side.

MR. FRANK B. RAE, the electrical engineer of Detroit, Mich., has been driven by the increase of professional work to take larger quarters, and has now moved into offices at 27 and 28 Cleland Building, 31st street, Detroit. Mr. Rae continues to make electric railroading and power transmission his specialty.

MR. WILLIAM H. MCKINLOCK, the founder and president of the Southern Electrical Supply Company, has just returned from St. Louis, and reports the Southern as doing a very brisk business, and says that under the new management, the prospects for enlarged future trade are very encouraging.

MR. CHARLES E. SHARP has been appointed manager of the Southern Electrical Supply Company. Mr. Sharp is a conscientious, pains-taking business man, and since his appointment (May 1) has gotten back a good many of the old customers of the Southern, besides new ones.

THE JENNEY ELECTRIC MOTOR COMPANY, of Indianapolis, have recently purchased a large amount of new machinery and heavy tools and now have very extensive equipments to handle the largest class of electrical generating machinery.

THE CENTRAL ELECTRIC COMPANY report a very active business in the Interior Conduit and Insulation Company specialties, a great many of the large buildings being equipped with this conduit in Chicago and elsewhere.

PROMINENT among the new apartment buildings in Chicago are the Erie, Mecca and the Groveland. All three of these are fitted with electric lights, the wire being supplied by George Cutter.

MR. E. ATKINSON, formerly connected with the Edison Laboratory at Orange, N. J., in charge of mechanical work, has accepted a position with the Standard Oil Company as salesman.

THE SUNBEAM INCANDESCENT LAMP COMPANY are the recipients of some highly flattering testimonials regarding their incandescent lamps.

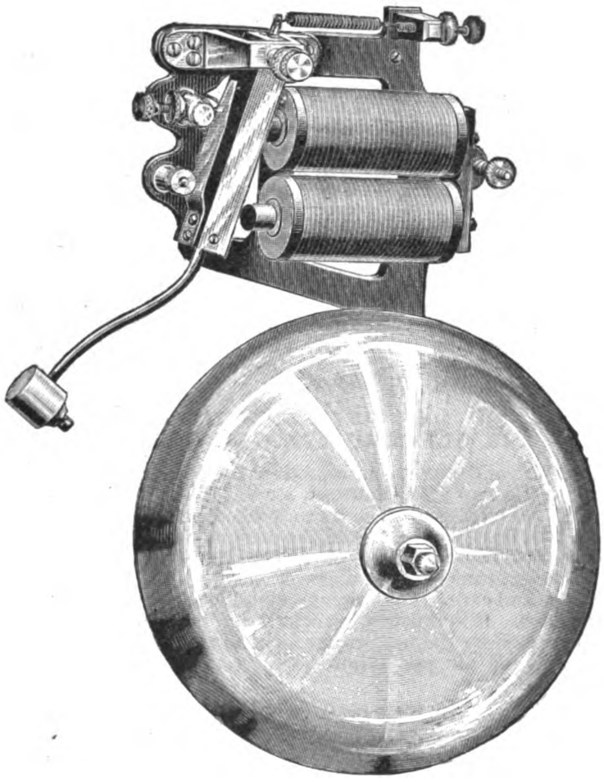
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

All successful advertising is cumulative in its effect and results.

THE "NOVELTY" PATENT HEAVY STROKE ELECTRIC BELL.

THE NOVELTY ELECTRIC Co., of Philadelphia, have recently brought out a new patented heavy stroke bell which has many new points of merit and is the invention of their ingenious superintendent, Mr. C. J. Miller. The bell has a large gong and is intended for fire-alarm and railway work where a loud and distinct stroke is desired. The principal feature of this bell is its long, movable magnetic circuit. The projecting cores into the holes in the armature give it a remarkably long stroke and quick action. The armature is in the same relative position to the cores at a greater, as it is at a lesser distance, and gives its final hard stroke when brought up to the main body of the core. The battery power required, size of magnets, and length of wire, remain the same as in bells of older type. The change from the old style of bell to the new with projected cores and corresponding holes in the armature permits a heavy stroke of 45 degrees on the gong. The main body of the core is made heavier than the projected ends, so as to present a still larger surface to the armature when brought into immediate proximity to them, which gives a powerful blow at the end. The bell is reliable in its action. It does away with many defects usually found in electro-mechanical gongs, also with the clock movement, doing away with the necessity of winding. All parts are made interchangeable and are furnished with damp-proof magnets, etc., when wanted for outside work. This bell has been adopted by the Pennsylvania Railroad Company. They have several of large size now in use for railroad signal and other heavy work.



"NOVELTY" HEAVY STROKE BELL.

ROYAL ELECTRIC CO., OF MONTREAL.

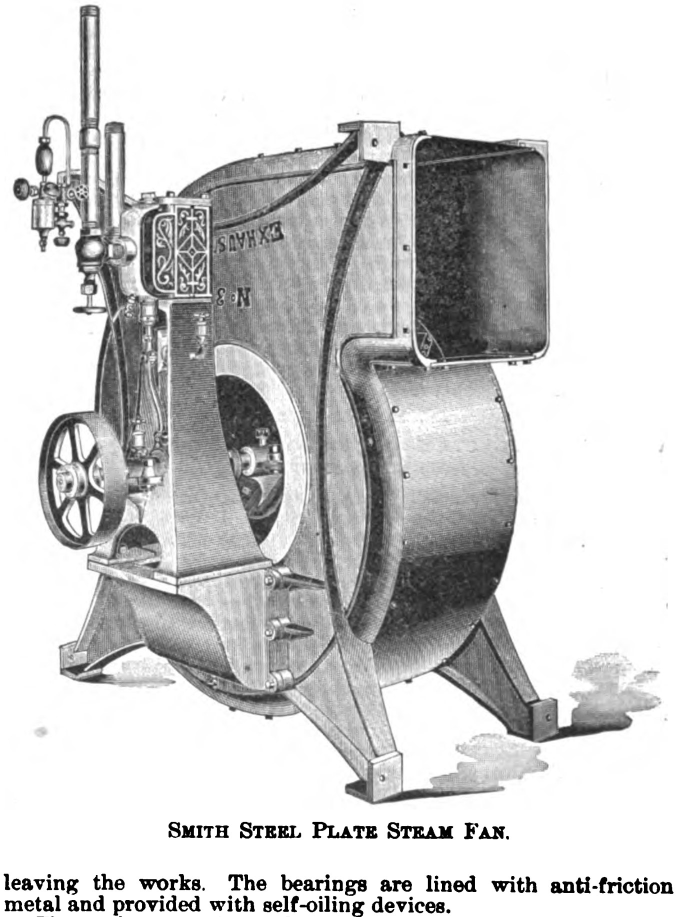
THE ROYAL ELECTRIC COMPANY, of Montreal, Canada, has secured the necessary authorization of the Canadian Government for its extensive scheme for the utilization of the water-power at the Chambly Rapids of the Richelieu River, the outlet of Lake Champlain. Operations will be conducted by its sub-company, the Chambly Manufacturing Company, as the Royal Electric Company is not permitted by its act of incorporation to engage in such enterprises; 25,000 h. p. will be available at low water, and plans are now being elaborated for its conversion into electricity and transmission to Montreal, 18 miles distant, to be utilized there for light and power. A series of dams is to be built across the river, upon which work will be commenced as soon as the water is low enough. Arrangements have already been made for line and other materials, and operations will be pushed vigorously so as to utilize a portion of the water-power as soon as possible.

Before deciding upon this project, the Royal Electric Company had separate examinations made of these rapids and those of the St. Lawrence River at Lachine, by eminent American and Canadian engineers. Though the American engineers consulted reported favorably upon the Lachine Rapids, the company, in selecting the water-power of the Chambly Rapids for development, were guided by the advice of the best Canadian engineers, who, it is to be supposed, understood better the conditions due to the peculiarities of the Canadian climate. Their report was that the formation of anchor ice and the backing up of the water would render the utilization of the Lachine Rapids impossible in winter.

As an example of the difficulties encountered, it may be mentioned that one channel in the Lachine Rapids at times gets blocked up with ice and is frozen in a solid mass down to the very bottom of the river.

THE SMITH STEEL PLATE STEAM FAN.

THE accompanying illustration shows a combination fan and engine built by the Huyett & Smith Manufacturing Company, of Detroit. The arrangement, as will be seen, is exceedingly compact. The engine is bolted directly to the frame of the fan, which is made of heavy angle iron and sheet steel with T and angle beams, the foundation being one solid cast plate. The fans are usually made for exhaust with the inlet on the opposite side from the engine, but where required for blowers, an opening appears on each side. They are built with the engine on either side, or are furnished alone if desired. The wheels and fan shaft are of steel, the former being accurately balanced and tested before leaving the works. The bearings are lined with anti-friction metal and provided with self-oiling devices.

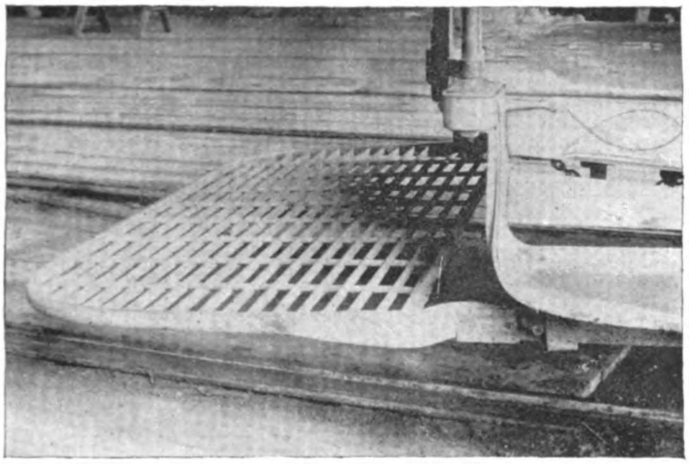


SMITH STEEL PLATE STEAM FAN.

The engines are of neat design and finish, specially constructed for this purpose with balanced piston valves, counterbalanced reciprocating parts, large bearings, perfect lubricating devices including sight feed lubricator, and are claimed to be durable and economical in operation.

THE JOHNSON "LIFE GUARD."

The secular press of some our country towns, and even of our larger cities is never happier than when discoursing upon the "Juggernaut" and describing the shrieks of the public as the "deadly electric car," gathers it in beneath its wheels. The unfortunates who perish through the agency of steam or cable traction are rarely eulogized to any great extent. As a matter of fact, if a man, or, indeed a woman or child will step in front of a rapidly moving car of any kind, an accident is apt to occur, and in such cases some of the guards in general use have proved of very little benefit to the victim. It is said by experts that the discomfort of being tumbled and shoved along over a rough road-bed by a wheel-guard is nearly as great as being run over by the wheel, and the ordinary form of "cow-catcher" is a most inhospitable arrangement, designed merely to get rid of an incumbent in the shortest possible time and without regard to his finer feelings.



The Johnson "Life Guard."

A totally different idea is embodied in the "Johnson" life guard, invented by Mr. T. L. Johnson, of Cleveland, Ohio, and in successful operation upon the Brooklyn Street Railroad Company's lines in that city. Its action will be seen at a glance from the accompanying illustration. Instead of allowing a pedestrian to be thrown aside in the way of other vehicles or beneath the body of the car to take his chances with the wheel guard, this device merely throws his feet from under him and carries him safely until the car can be stopped, thus avoiding any greater injury than a bruise or sprain. The forward edge of the guard is rounded and padded and has a strong, but yielding surface. It is attached to the car by means of brackets under the steps, may be readily and quickly applied, and since its usefulness has been thoroughly demonstrated is being extensively adopted. We have seen statements of a number of interesting cases in which it has proved thoroughly successful.

A COMPLETE ELECTRIC SYSTEM FOR THE DETROIT CITIZENS' STREET RAILWAY CO.

After carefully investigating the merits of all the leading electric railway systems, the Citizens' Street Railway Company, of this city, awarded the Detroit Electrical Works the entire contract for the equipping of their Jefferson avenue line with electricity. The contract includes the entire power station plant, overhead lines and motor equipments, as follows: The power station steam plant is to consist of three horizontal return tubular boilers 66 inches in diameter, 16 feet long, each to have sixty 4-inch flues; and three 14–24 x 14 Westinghouse automatic compound engines, with all necessary apparatus, such as feed-water heater, pump, injectors, piping, smokestack, etc.

The power station electric plant is to consist of three 100 K. W. multipolar railway generators of the Detroit Electrical Works, latest type. Also, slate switchboard of the latest and most improved design, with all instruments and attachments necessary to make a complete electric plant.

The overhead construction will consist of two No. 0 B. & S. gauge hard-drawn copper trolley wires, with necessary feeders and guard wires, supported on Milliken iron poles. The standard to be used for that portion of the avenue which is 70 feet wide from curb to curb, and their extra heavy type where the avenue is 80 feet from curb to curb.

The motor equipment will consist of twelve 40 h. p. motor equipments of the Detroit Electrical Works standard type.

If the work is not delayed by injunctions or obstructive measures of that character, it is expected that the plant will be in operation in about 75 days. As this will be the first line running through the centre of the city of Detroit to be equipped with electricity, the plant is to be made a model one in every respect, to which end the Detroit Electrical Works are making provision for building it on the most improved lines, and including all of the latest appliances.

As this contract is only one of a number that have lately been awarded the Detroit Electrical Works in face of sharp competition by manufacturers of other electric railway apparatus, it shows plainly that this company is fully substantiating their claims, that their equipments, using one motor geared to both axles, have great advantages. The extensions to the factory of the Detroit Works are now nearing completion, and they expect soon to have it equipped and in operation, when they will undoubtedly be in better position to push the business as its growth requires.

THE LUNKENHEIMER BRASS MANUFACTURING COMPANY.

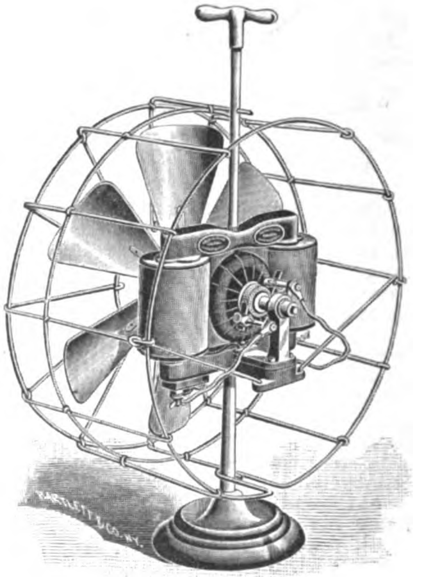
A very ornamental catalogue for 1892 has just been issued by the Lunkenheimer Brass Manufacturing Company, of Cincinnati, Ohio, giving detailed descriptions of the various brass and iron goods and specialties for steam, water, gas, oil, etc., made at their works. The book contains 98 pages, is handsomely printed and bound, and profusely illustrated with excellent wood cuts. The aim of the compiler has been to make the work plain, practical and compact, in addition to which he has succeeded in making it highly attractive.

THE BUCARAMANGA PLANT.

In our issue of May 11 we inadvertently stated in the description of the electric light plant at Bucaramanga, U. S. of Colombia, that the plant had been installed by Mr. Julio Jones, for the Thomson-Houston International Electric Company. The fact is that Mr. Jones not only installed the plant on his own account, but is owner of the entire property. The enterprise is the more creditable and noteworthy.

THE ELECTRO-DYNAMIC CO.'S FANS.

The fan and motor combination introduced by the Electro-Dynamic Co., of 224 Chestnut street, Philadelphia, is simple, durable and effective. The motor embodies all the latest improvements that have been made in the designs of the company's larger machines; is fitted with self-oiling bearings, has a tempered copper commutator, runs with no appreciable noise and requires but little attention and care. The fan is twelve inches in diameter and has four blades. It is finished in nickel or polished brass, as desired; and, operated by the motor, has a capacity of moving about 1,000 cubic feet of air per minute, which gives it ample capacity to ventilate an apartment of ordinary size. The record for this fan is 5,000 hours, running without injury to bearings and with no expense beyond one renewal of the brushes, and turning off the commutator on one occasion.



The Electro-Dynamic Co's Fan Outfit.

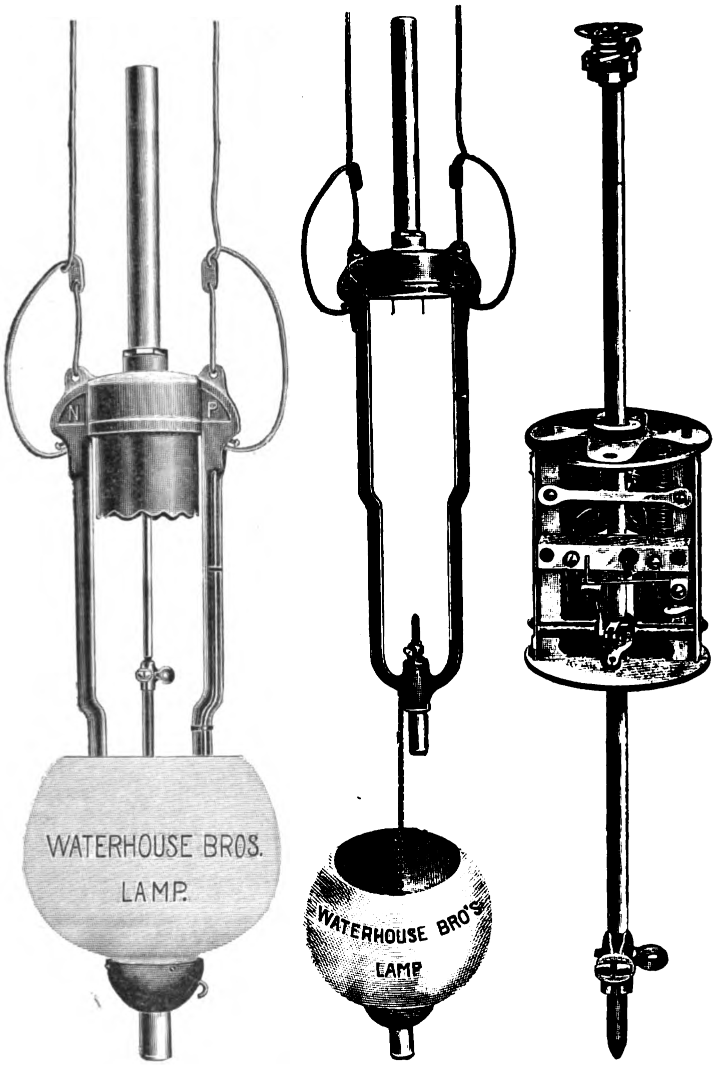
The Electro-Dynamic Company manufacture a fan having two blades, with a capacity to move about 600 cubic feet of air per minute, which has received particular commendation as a desk fan for use in offices during the heated summer months, and also small motors for running sewing machines, watch makers' lathes and similar small apparatus.

THE DETROIT ELECTRICAL WORKS.

A recent issue of the *Detroit Evening News* contains an interesting article on the above institution, which was started in 1879 and now has a capital stock of $2,000,000 of which $1,000,000 has been issued. The old factory of three stories, 150 by 120 feet, is being supplemented by another also three stories, 100 by 120 feet. The steam plant aggregates 500 h. p., 220 hands are employed and the output last year reached $750,000. The electric railway system is now in use on 29 railroads, and contracts have lately been closed for other roads at Newark, N. J.; Brooklyn, N. Y.; Cleveland, O.; Springfield, Ill.; Chicago; Kansas City; Dubuque, Ia.; Omaha and Galveston. The works are also building a large quantity of electric power apparatus, motors and general electrical apparatus. The officers are Hugh McMillan, president; W. A. Jackson, vice-president; W. H. Wells, secretary, and Louis Warfield, general manager and treasurer.

WATERHOUSE BROS'. ARC LAMP, FOR ARC OR INCANDESCENT CIRCUITS.

WATERHOUSE BROS., of Hartford, Conn., are now manufacturing what might practically be called a universal arc lamp. The lamp is manufactured, and can be sold, in two separate parts—the frame and works as shown in Figs. 1, 2 and 3. The same frame and carbon rod is used for any kind of current, while the works, as shown in Fig. 4, for incandescent, differ slightly from those for arc circuits, but all fit the same frame. All parts are made entirely by machinery, without the aid of hand tools, thereby insuring exact duplicates and interchangeability. By uniting all the working parts of these lamps in a cage constructed of a single casting, shown by Fig. 4, an exact adjustment of the parts is secured; and they are rigidly held in their places. This enables the manufacturers to produce lamps so that their action will be exactly alike, strong and perfect, and gives the operator a lamp that can be quickly and inexpensively repaired or changed from one circuit or candle power to another without removing the frame from its hanging position and without the aid of skilled labor.



FIGS. 1, 2 AND 3.—WATERHOUSE ARC LAMP.

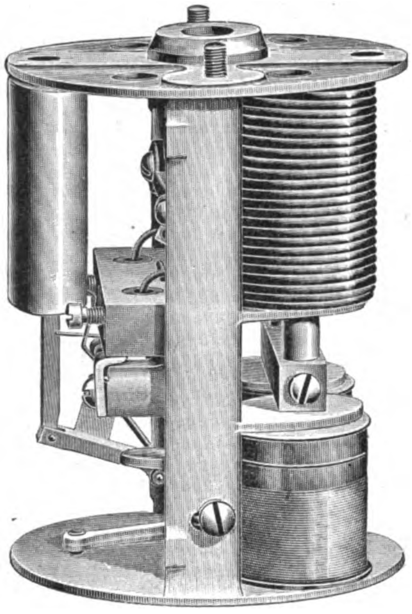


FIG. 4.—WATERHOUSE ARC LAMP.

There is but one insulating washer in or about the lamp, the top of the frame being filled with an insulating cement in which go the terminals and anchor plate to which the works, as shown in Fig. 3, are fastened by two bolts, while the lower carbon holder is held in position by cement also. The lamp is weatherproof and requires no hood when exposed to the elements. The globe holder is of cup-shape and dust-tight for inside use, so no sparks can fall from the lamp, and it is properly drained for outside use. It is made to swing down from the lamp so that it and the globe can be easily tipped and cleaned without unfastening the screws.

The advantages of the clutch form of lamp have been retained, and by a peculiar device on the top of the carbon rod, the drop or overfeeding, is avoided. This feature is particularly noticeable when the lamps are burning on incandescent circuits; the feed being so fine and positive, that the see-saw effect, so often objected to, is entirely overcome, giving a steady and even light from both lamps in series.

NEW YORK NOTES.

MR. W. F. D. CRANE, who has been widely and favorably known as manager of the railway department of the Engineering Equipment Co., has recently become connected with the H. W. Johns Manufacturing Co., 87 Maiden Lane, New York, and will hereafter have charge of the electrical department of that company. Announcement has been made of the consolidation of the moulded mica insulating business of the Gould & Watson Co., of Boston, with the Johns-Pratt Co., of Hartford. Mica trolley line insulating materials have entered into the construction of numerous electric railways since the beginning of electric railway enterprises, and are so well known as to have become standards of use in overhead construction. The Vulcabeston insulating material, manufactured by the Johns-Pratt Co., is also well known to makers and users of electrical machinery. Mr. Crane will give his special attention to the further development of the already large business of the H. W. Johns Manufacturing Co., selling agents of these materials.

J. G. WHITE & Co. report their construction business prosperous, and say they have seven electric railway contracts on hand mostly with iron pole construction. Among those recently closed are 7½ miles for the Baltimore Traction Company, 16 miles for the New Orleans and Carrollton Railroad, and 11 miles for the Central Railroad Company of Baltimore.

MR. CHARLES F. G. KOPSCH, electrical engineer of Sidney, N. S. W., is on a visit to this country, and has been in New York en route for San Francisco. He has been spending considerable time in Europe, and will represent various firms on his return home.

MR. LUTHER STIERINGER has just returned from a Southern trip of recreation, and now proposes to hie away to the wilds of Minnesota, in order to ascertain whether he would rather spend his time and fortune in the far North than down South.

VULCA DUCTS.—Considerable interest in local lighting circles was created last week by the statement that the Interior Conduit & Insulation Co. had brought suit against the Eureka Electric Co for infringement of its patents in putting conduits into the fine new Seabury Building on Maiden Lane. It appears that the Eureka Co. have the electrical contract for the building, and have used the Vulca duct made by the New York Insulated Wire Co. Inquiry into the subject elicited the fact that the New York Insulated Wire Co. had at once stepped forward and assumed all the responsibilities of the case. In an interview on this subject last week, Mr. J. W. Godfrey, the manager of the New York Insulated Wire Co., said: "We no sooner heard of this action on the part of the Interior Co., than we took up the gauntlet. In fact, after so many threats, they would have looked very ridiculous if they had not gone for somebody; and I don't think they have improved the matter by attacking an entirely disinterested third party who only bought what he knew to be the best in the market. I would like to say for the information of the public and the guidance of our many friends all over the country, that we are going right ahead, and that while we have not sought this litigation, we are advised by the best legal and patent talent in the country that in nowise do we infringe. The idea of running wires through tubes is a very old one, and except that, our material, processes and methods are all our own, worked out with great skill and already tested by experience in all kinds of work. We will protect all who use our Vulca ducts just as completely as those ducts protect their wires for them; and I need hardly say that our company has the entire confidence of the electrical trade, won through several years of upright dealing. The truth of the matter is that our ducts are by long odds the best. If they were not, the others would control the field; but as we have got to the top by merit, it is now sought to damage our prospects by this kind of intimidating litigation. But that dodge won't work in such an intelligent community as ours."

THE DETROIT ELECTRICAL WORKS have been compelled by the active demand in the East for their railway, power and general electrical apparatus, to open a New York office. It has been located at rooms 11 and 311 Metropolitan Telephone Building, 18 Cortlandt street. It will be in charge of Mr. T. W. Warfield as district manager. The works have also opened an office in Boston at room No. 23 Fiske Building. The many patrons and friends of the concern in the East will greatly appreciate the convenience of these new offices, and the works will also be put in much closer touch with the large market that exists east of Detroit for the excellent products of the works, to any demand for which the increased facilities will now prove equal.

THE NEW YORK ELECTRICAL WORKS, 161 Washington street, New York, are now settled in a thoroughly equipped factory for the manufacture of general electrical specialties. Some ingenious and simply constructed quick-breaking double and single pole switches are among the devices made by this company. They are also sole makers of the celebrated B. & M. trolley wheels. These wheels are made of a metal which is a special "bronze," of a bright silvery color, very tough, and which does not tarnish. Wheels made of this metal have a record of 10,000 miles with very little perceptible wear. The company make a special offer, that upon the return of worn-out wheels they will allow 20 cents per lb. for the old metal.

"IT WAS NECESSARY—for us to move into more desirable and larger quarters" is the reason given by J. Jones & Son, who are now located conveniently on the second floor at 39 Vesey street. This company have of late been doing such an amount of special work for large companies located in the downtown district, that after due deliberation it was decided for the convenience of both manufacturers and patrons to make the above change. The intention is to carry a complete stock of supplies, and continue as well the making of electric light and railway supplies.

THE CHILLICOTHE, O., ELECTRIC RAILWAY & LIGHTING CO. has just been organized by Geo. F. Woolston and associates, of New York. The company will erect an arc and incandescent light station. They have also bought out the horse railroad company and will at once convert to electricity beginning with a 10-car equipment. Power will be furnished from the lighting station.

THE THOMSON-VANDEPOELE MINING COMPANY, of Boston, have recently sold to the Boston and Montana Mining Company three M. P. 180 h. p. generators for use in its electrolytic plant at Great Falls, N. H. The plant will be similar to the Lewissohn plant at Pawtucket, R. I., and construction will be proceeded with at once.

MR. W. R. MASON, the ubiquitous and very active genera manager of the Railway Equipment Co. was in the city last week, making agencies and securing them for his own territory. For the present business will be carried on at 11 Adams street, Chicago.

THE MICA ASBETITE COMPANY, 444 Pearl street, this city, are in receipt of several handsome orders for their railway specialties from different points in the West where electric railways are in course of construction.

THE JOSEPH DIXON CRUCIBLE CO., of Jersey City, have just issued a new and useful catalogue, including graphites, plumbago, etc., now so largely used in the electric arts.

NEW ENGLAND NOTES.

THE EDDY ELECTRIC MANUFACTURING COMPANY, of Windsor, Conn., are making rapid progress with their new extension and expect to occupy it some time in July. The new wing measures 154 feet long by 50 feet wide, and will have three stories. A large new tubular boiler has been put in, and a 150 h. p. Ball & Wood engine will be installed very soon, which will be chiefly used for testing purposes. The Eddy Company have been extremely busy lately, and have been forced to run 24 hours a day. Their business this year is just about 50 per cent. ahead of what it was in 1891, and the increased facilities when ready will be very welcome to the management. They are at present building four 250 h p. generators for furnishing power for the Manufactures and Liberal Arts and sundry buildings for the World's Fair, for which they received the contract some months ago. They are also building two 100-kilowatt railway generators for the electric railway at Atlanta, Ga., and two 100-kilowatt railway generators for the West End road in Rockford, Ill. Altogether, their factory presents a busy scene, and their business prospects never looked brighter than at present.

THE EASTERN ELECTRIC SUPPLY AND CONSTRUCTION COMPANY have for some time, owing to their largely increasing business, been looking for more commodious quarters, and have at last decided to move to 77 Franklin street, and 80 Arch street, Boston, where they will have much more room to transact their business. Their new quarters are well known as having previously been occupied by the Pope Manufacturing Company, and are most centrally situated and extremely convenient. They will occupy the whole ground floor and basement, will have about 8,000 square feet of floor space, and expect to get settled about June 1st.

THE EASTERN ELECTRIC LIGHT AND STORAGE BATTERY COMPANY, of Lowell, Mass., have secured the contract for the complete electric equipment of the buildings of the new Rotch Spinning Corporation of New Bedford, Mass., and also a 100-light storage battery equipment for the Cambridge House of Correction, Cambridge, Mass. They are also equipping the new offices, stores and waiting-room of the Lowell and Suburban Street Railway Company with storage batteries, which will be charged from the trolley wires.

ALBERT & J. M. ANDERSON, of Boston, have appointed Mr. Robert W. Blackwell, 39 Victoria Street, Westminster, London, as their agent in England. Mr. Blackwell will keep in his office a complete line of samples of the well-known Boston trolley, and all kinds of the Ætna insulated trolley line material, and will be glad to show them to all interested in the development of electric railways in England and other European countries.

MR. E. W. FYLER has resigned his position with the Holtzer-Cabot Electric Company, of Boston, and has gone into business for himself with headquarters in the basement of the Exchange Building, Boston. Besides doing a general electric construction business, Mr. Fyler has taken the agency for the International typewriter, and will be glad to have a call from his friends at his new quarters.

THE ENTERPRISE ELECTRIC COMPANY.

MR. W. C. MCKINLOCK, formerly with the Central Electric Company, of Chicago, and later manager of the Southern Electric Supply Company, of St. Louis, for which company he built up a very large and successful business, has resigned and organized the Enterprise Electric Company, which will deal in general electrical supplies of all kinds for telegraph, telephone, electric light and power work with a handsome store and offices at No. 313-315 Dearborn street, Chicago. Mr. McKinlock has a host of friends in the electrical business, and is well known for his push, ability and energetic business qualities and the success of the new company is a foregone conclusion from the start.

A number of very valuable specialties have already been secured and the concern will be the local agents for Kerite wire, for which Mr. W. F. Cushing is the general Western agent, and will also handle a line of goods manufactured by the Western Electric Company, of this city, as well as other valuable specialties. An exceedingly large stock in all branches will be carried enabling prompt shipments.

Mr. F. P. Hill, late of the Southern Electric Company, of St. Louis, and Mr. W. F. Richardson, formerly of the Central Electric Company, of Chicago, are connected with Mr. McKinlock in the new venture, and it is probable that Mr. Hill will be the secretary of the company. The promoters of the new supply house are all bright men, familiar with the business in all its branches and with a large circle of friends in the electrical field in all parts of the country form an exceedingly strong personnel which will insure a large amount of business being done from the outset.

THE
Electrical Engineer.

VOL. XIII. JUNE 1, 1892. No. 213.

THE UTILIZATION OF EXHAUST STEAM FOR HEATING BY THE SPRINGFIELD, ILL., ELECTRIC LIGHT & POWER COMPANY'S PLANT.

BY

H. Dorman Collins.

SPRINGFIELD, Ill., offers to-day a very interesting exemplification of high economy in central station operation, and I venture on a description of the plant I have recently seen there. Anything which tends to increase the dividend and bring about more economical operation will be eagerly welcomed by the central station man, who is usually very much on the alert to enlarge the productiveness of his plant.

In the early days of central stations only lights were operated and these called generally for the running of the plant only at night; but with the advent of the electric motor for power work came the opportunity of more continuous working of the plant and largely increasing the earnings as the machinery performed more hours of service, bringing in a larger amount of money upon the investment. It is therefore not to be wondered at that a method of utilizing the exhaust steam and turning into money that which has formerly gone to waste should be attracting the attention of those engaged in central station work and receiving the introduction and adoption it deserves, when it is remembered that by this means many a station whose returns are exceedingly slim, or none at all, can be rendered profitable. Such a plan, complete in every particular and worked out to its minutest detail, is the "Holly Combination System" for the utilization of the waste steam of central station plants, which is manufactured by the American District Steam Company, of Lockport, N. Y. This system was described in a recent number of THE ELECTRICAL ENGINEER.

With keen foresight the officers of the Springfield Electric Light & Power Co., of Springfield, Ill., recognizing the advantages of realizing on the exhaust product of their station, and after a careful investigation of the system, decided to add it to their plant, and the results have shown the wisdom of their course and the stockholders have no reason to regret their action, which has proved more successful than their most sanguine anticipations.

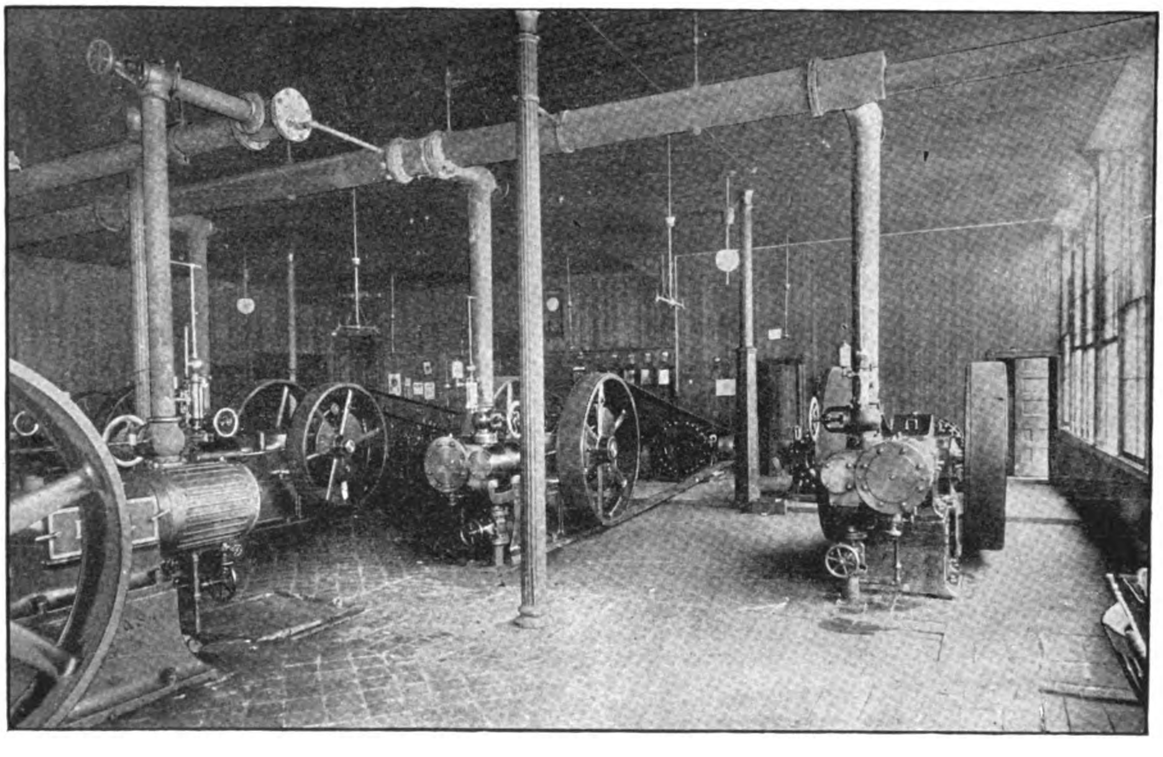

FIG. 1.—ENGINE AND DYNAMO ROOM, SPRINGFIELD, ILL., ELECTRIC LIGHT AND POWER CO.

The accompanying illustrations Figs. 1, 2 and 3, show this plant very clearly. It comprises six 50-light Thomson-Houston arc machines, belted direct to Ideal engines of 125 h. p. each, made by the well-known engine builders, A. L. Ide & Son, of Springfield, Ill. In connection with the arc lighting machines an exceedingly novel arrangement for keeping the armatures cool is employed. A small 2 h. p. motor runs a Sturtevant blower located beneath the floor, which forces air through a 10-inch main and 4-inch supply pipes upon the armature of each machine. This method of ventilation has been found to be highly satisfactory, and the fact that an armature has never been lost from any cause, speaks highly for the efficiency of the treatment. The dynamos connect with a switchboard so arranged that any dynamo can be placed on any desired circuit. The incandescent portion of the plant consists of one 650-light Thomson-Houston alternating current machine and one 1,300-light machine of the same make and style. These machines are connected to a handsome switchboard equipped with all necessary switches, instruments, etc., and are also driven by Ideal engines; 150 arc lamps of 2,000 c. p. capacity each and 250 incandescent lamps of 20 and 50 c. p. are run for street lighting by this plant, which also furnishes current for some 75 commercial arc lamps, and on special occasions for from 25 to 50 more arc lamps and incandescent lamps equivalent to the capacity of the alternating dynamos. In addition a motor circuit is in operation, current being supplied by a 50 h. p. generator to run some 25 motors of capacity varying from ⅛ to 10 h. p., three of which are running elevators.

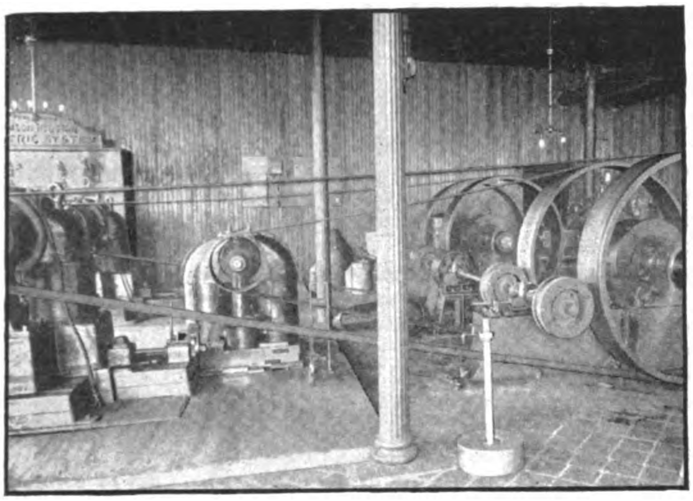

FIG. 2.—SPRINGFIELD, ILL., ELECTRIC LIGHT STATION.

The power plant for furnishing current for the street railway is operated by the station and consists of three 100 h. p. Thomson-Houston railway generators driven by three 125 h. p. Ideal engines, belted direct. A very ingenious friction drive has recently been installed to enable either one or two of these engines to drive the generator, furnishing current for the motor circuit. This is shown in Fig. 2.

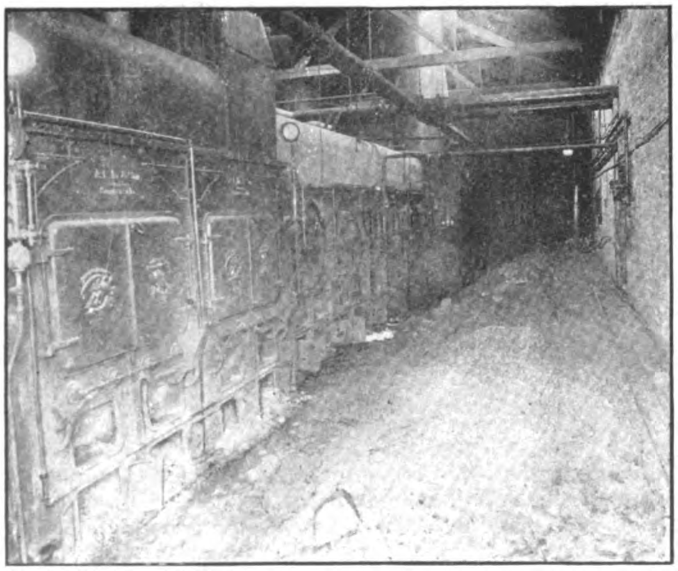

FIG. 3.—SPRINGFIELD, ILL., BOILER ROOM.

In the boiler-room are nine boilers manufactured also by A. L. Ide & Son, two of which are of 100 h. p. capacity each; three of 80 h. p. each and the remaining four of 60 h. p. respectively, and which furnish steam for the engines.

The lightning arresters which were formerly placed in the top of the tower from which are distributed the circuits, have recently been changed and lowered in the tower to a level with the ceiling of the dynamo-room. Pipes run so that in case of an arc from lightning they can be surrounded with live steam. This precaution was taken from experience gained from a recent storm when an arc formed by the coming in of the lightning upon the arresters almost resulted in a disastrous fire.

The exhausts of the engines are connected to the mains of the steam heating plant, Fig. 4, which are 8 inches in diameter and which shortly after leaving the station branch into smaller mains, 6 inches in diameter. This exhaust steam is being furnished for heating to about 16 business blocks, and not the least difficulty has been found in securing in the immediate vicinity of the station all the business in this line that can possibly be taken care of.

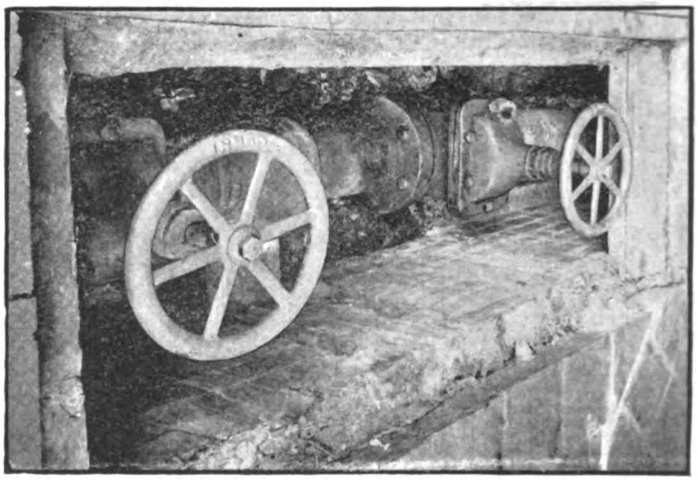

FIG. 4.—CONNECTION OF EXHAUST WITH STREET STEAM MAINS.

Ordinary radiators are employed and something over 2,000,000 cubic feet of air space in these buildings is now being heated, and this will be increased to over 3,000,000. The amount of power of exhaust steam at present in service at a pressure of about 5 lbs. is 200 h. p. At first contracts for steam heating were taken by the company at a price of $2.50 per 1,000 cubic feet of air space per year, but they are now based, and more properly so, upon a charge of 20 cents per foot of direct radiation per year, or 25 cents on indirect radiation. The use of this system, while yielding a most generous profit to the station, is also cheaper for the consumer, as he can dispense with the services of an engineer or janitor to look after his boiler and steam heating apparatus whom he has to employ when operating his own steam heating plant; and from the fact of steam being on day and night it has been demonstrated that 25 per cent. less heating surface is required than where the heating is done by boilers in the buildings; in many cases this percentage of radiating surface has been taken out on account of the heat being greater than required. An average estimate for the amount of heating surface required is one square foot of radiation to 50 cubic feet of air. At the station an automatic device is provided to prevent the pressure exceeding 5 lbs. and the 5 lbs. back pressure on the engines is compensated for by an additional 5 lbs. pressure on the boilers. The limitation of area of supply for the highest economy in operation in any territory which is well built up is estimated as about half a mile, but even buildings at considerably greater distances can be supplied with good results. It is also perfectly safe to take on at least one-third more customers than the total number which the exhaust steam of the station is capable of supplying, as, if necessary through the most severe weather when the demand is at its greatest, a small amount of live steam from the boilers can be conveniently supplied, arrangement being made in the system for such a contingency.

The additional amount of fuel required during the time of heating does not exceed 5 per cent. The investment upon the installation of the steam heating system is very reasonable, and wear and tear on the pipe junctions, connections, etc., is practically nothing, as they will last for years and repairs will be very low. The receipts from the heating are practically all profit in the case of a plant operating both day and night, where a portion of the engines are running all the while driving dynamos, furnishing light and power.

Not only are the central station men enthusiastic over the success of the system which they regard as the best-paying investment in the business, the profits being at least double that from light or power, but the consumers are equally delighted with the excellence and absolute reliability of the service, and it is safe to predict that the time is at hand when the system will receive the full consideration and use that its merits and advantages entitle it to.

The day is not far distant either when the householder will be able to buy his heating from the central station in his vicinity as he now does his electric light, water or gas, and will no longer struggle in frigid desperation with the malignant hot-air furnace, which, just when the cold snap comes along, evinces a persistent disposition to force the hot air into the cold-air shaft instead of the room, and shifts its scene of operation with every change in the wind, and he will once more think that life is really worth living.

THE ECONOMY OF CONDENSING ENGINES OVER-RATED.

BY

D H Babcock

It is safe to say that electricity in its varied developments has absorbed more capital in the brief space of a few years, than any other element or enterprise has ever before done in the same space of time, since man first broke into nature's storehouse. It is for this reason that the best scientific minds are enlisted in the cause. The best engineering is demanded. Discussion and experience are settling doubtful points, and are constantly making new discoveries in the field of economical application of known results. All this wonderful activity is in obedience to the demands of capital. Capital commands the best service obtainable, whether on sea or on land, whether on the earth in the light of day, or in the deepest mines where night reigns perpetual. And why is capital thus exacting? It knows well that thrift comes from enterprise, activity, invention. Capital undertakes great enterprises for the profits believed to be in them. It makes investments from which better interest is expected than the banks are able to pay. For this reason capital has invested in these electrical enterprises, and if they are not made to pay it will know the reason why. While the field is a hopeful one and success has been achieved at some points where the most favorable conditions exist, yet there is need of "the highest grade of engineering supplemented by close business management" all along the line. Good engineering may construct a plant perfect in all details but loose business management may also conduct the enterprise to a failure.

In a previous paper I showed that some companies are deriving a large profit from their *exhaust steam.* This is carried in underground pipes and sold for heating buildings; an article for which there is a ready sale eight months of the year. Exhaust steam being a by-product, it follows that the income realized from its sale is nearly a clear profit. There does not seem to be any good reason, then, why an electric plant should not avail itself of this source of income, where the boiler plant is favorably located for the work. In cases where condensing engines are used, this is given as the reason why the use of exhaust is not called for. In the minds of some managers the fact that condensers are in use closes the case; but does it?

A plain cylinder will use 10 per cent. only of the heat units represented by the fuel consumed. If you add a condenser you can increase the efficiency of your engine 25 to 33 per cent., that is, you then use 13 per cent. instead of 10 per cent. of the heat units. Where is the balance of your heat units? Making due allowance for radiation from boilers and engines, it may be said for a fact, that at least 80 per cent. of the total heat units flows away in the large amount of hot water leaving the condenser. If the manager can make no better use of his steam, then three per cent. is a saving, provided he has free water without pumping. If the company pay water rent or run a pump, it is doubtful if there is any economy. If the condenser is advisable he can run it during the part of a season when there is no market for heat; construct a system of street mains to connect with the exhaust pipe, and disconnect the condenser during the heating season. Each 100 h. p. of boilers will heat 1,000,000 cubic feet of space from the exhaust, worth approximately $3,000 to $5,000, when in continuous use during the season for heating. Nothing like this amount of value can be shown to follow the use of condensers; besides, as has been shown, the condenser does not bring any relief from the hours of idleness each day, when the whole plant is "lying idle and unproductive of anything but interest account."

The case is simply this: Given a certain amount of fuel to be burned under a battery of boilers which produces in steam a certain number of heat units. The best we can do in engine work leaves more than 80 per cent. of these units still in the steam after it has passed the engines, and fully 80 per cent. of the remainder escapes in the water from the condenser if one be in use.

Providing conditions are favorable for turning this 80 per cent. of heat units into money, is it "close business management" if this important source of revenue is neglected?

SOCIÉTÉ INTERNATIONALE DES ÉLECTRICIENS.

The following gentlemen form the council of this society for the current year: President, M. L. Raymond, Director of the Ecole Supérieure de Télégraphie; vice-presidents, MM. Bouillhet and Potier; secretaries, MM. Sarcia and de la Touanne; members of council, MM. Abdank-Abakanowicz, Baille, Baudot, H. Becquerel, J. Boulanger, Brüll, Cance, Cornu, Fribourg, Friedel, Gaudry, Hillairet, Krebs, Meyer, Mildé, Raffard, Tripier, Vaschy, Violle, and Vlasto.

At a recent meeting of the Société Internationale des Electriciens, M. Rechniewski gave the results of some investigations by M. Labour and himself, on the relations between energy dissipation in, and cooling surface of, dynamo armatures. M. Rechniewski allows a rise of 50 degrees C. above the temperature of the surrounding atmosphere. The figures he arrived at in the case of three 2-pole drum machines were 7.14, 6.9, and 7.5 sq. cms. per watt dissipated. With vigorous internal ventilation, only 4.25 sq. cms need be allowed. Finally, in certain armatures of multipolar machines with open interiors and vigorous ventilation, M. Rechniewski concludes that 3.3 sq. cms. per watt dissipated will suffice.

THE RELATIONS BETWEEN ENGINE AND DYNAMO IN RAILWAY WORK.

BY

Chas. Hewitt,

Mr. Wm. Church in his article on "Points on Railway Power Stations" published in The Electrical Engineer of April 27, seems to be more familiar with the steam engine than with the dynamo. He says: "An electric generator can stand an overload, or even an excessive overload, provided it does not have to stand it long. *The question is simply one of heat.*" This very question of heat is one of the worst troubles that engineers have had to contend with. Further, it is not simply a question of heat, but of E. M. F. as well. The E. M. F. of the best compounded dynamos will fall off rapidly with much of an overload, and the frequent lowering of the initial pressure is disastrous to the satisfactory running of the cars. Further, he states that an engine has no such capacity for excessive overload as a generator, but is able to stand an overload of from 20 per cent. to 25 per cent., assuming that the engine is honestly rated.

Following Mr. Church's argument I have reached the following results which differ rather materially from his. Many tests of street railway power stations have shown that for moderate size plants, say 25 cars and over, the *average* load is very close to ⅔ of the maximum load. For smaller plants the average load will fall as low as 50 per cent. of the maximum and even less. In all cases the dynamos should be of sufficient capacity to carry the maximum load without lowering the E. M. F. For maximum efficiency of operation I would suggest that the engine should have a rated capacity half way between the average load and the maximum load. The engine would then operate at an average load of 80 per cent. of its rated capacity, and would only have to carry momentary maximum loads 20 per cent. above its rated capacity, which is within Mr. Church's limit. Assuming a specific case, say we start with a dynamo of 100 e. h. p. The average load would be 66.6 e. h. p. Adding one-half the difference between the average load and maximum load and allowing 10 per cent. for loss in the dynamo we find that the engine should have a rated capacity of 92 h. p. The boiler should be slightly in excess of the average load on the engine, to allow for loss in pipe, etc. Say, for the case in question, we allow 15 per cent.; the boiler would then have a rated capacity of 86 h. p. The arrangement would then be as follows:

Dynamo	100	e. h. p.	rated
Engine	92	"	"
Boiler	86	"	"

Such an arrangement as the above would, I believe, give the highest efficiency of operation, were it not for the fact that short-circuits and similar accidents will persist in occurring even with the best of management. To meet such emergencies the engine should have a margin of power above what the above reasoning would call for, and for plants of any considerable size a spare engine and dynamo is almost a necessity to prevent a shut-down. Further, no plant that runs as continuously as most street railways do should be without a spare boiler. In view of these facts it seems advisable to have the dynamos of ample, but not excessive capacity, and the engine of a rated capacity equal to the power of the dynamo. This I believe is the general practice at the present time. Mr. Church's criticism about "rule of thumb" then does not seem to be so just as he would have us believe.

I would also take exception to his statement that "the engine and dynamo can be fairly trusted to take care of themselves since any ordinary repairing can be quickly made between running hours." If railway companies followed this advice they would get but poor satisfaction. Most roads start at between 5 a. m. and 6 a. m., say, 5.30, and do not stop until 12 or 1 o'clock at night. The hours for repairing would then be from, say, 12.30 to 5.30 a. m. —not the most convenient time for doing even the most ordinary repairing.

DR. JACQUES' EXPERIMENT SHOWING WHAT ELECTRICITY IS.

BY

Victor M. Berthold

In his adress delivered before the American Academy of Arts and Sciences at its recent social meeting at the residence of Hon. Martin Brimmer in Boston, Dr. Jacques brought forward a crucial experiment that would seem to go a long way towards showing that the electric fluid is identical with the ether that fills all space. The experiment at least demonstrates that a current of ether possesses both qualitatively and quantitatively the same properties as a current of electricity.

Although the address has been reprinted in many of the electrical journals, we may say, briefly, that the experiment consists in measuring, with a peculiarly novel and sensitive galvanometer, the electrical effect of the current of ether produced by the rapid motion of the galvanometer through space as it is carried along by the earth in its journey around the sun, combined with its well-known movement towards Hercules.

At the close of Dr. Jacques' address before this learned body of scientists, the discussion took but one path, that of commendation of the beauty and completeness of the experiment.

In an editorial article, printed in The Electrical Engineer of May 18, 1892, the opinion is expressed that Dr. Jacques' experiment does not prove that the electric current is a bodily forward movement of the ether, but does show, what had previously been shown by Prof. Rowland, that a moving electrified body is equivalent to an electric current.

It is to be regretted that the writer of this editorial had not the good fortune to be present and listen to the remarks following Dr. Jacques' address, where the relations between Dr. Jacques' experiment and Prof. Rowland's experiment were fully discussed. It did not occur to this body, comprised of our leading mathematical electricians, that Dr. Jacques was merely proving, in another way, what Prof. Rowland had already proved, but, on the contrary, it was the universally expressed opinion that Dr. Jacques had taken a marked step in advance of our present electrical knowledge.

Nor did it occur to the late Prof. Clerk Maxwell that the movement of a pair of oppositely electrified plates relative to the ether would prove the same thing that would be proved by rotating an electrically charged body about a magnetic needle; for that great mathematical electrician anticipates both the experiment of Dr. Jacques and that of Prof. Rowland (*Electricity and Magnetism*, §§ 771 and 772), though there is this marked difference that, while he describes the experiment that Prof. Rowland afterwards made, almost in detail, he says of Dr. Jacques' experiment: "Since this velocity is about 288,000 kilometres per second, it is impossible to make the experiment above described." It remained for Dr. Jacques to conceive of utilizing and to utilize the enormous velocity of the earth in its journey through space to move his charged plates relative to the ether.

ELECTRICITY ON A SOUTHERN FARM.

BY

A. F. McKissick

THE recent application of the electric motor to ginning and pressing cotton, cutting up feed-stuff, threshing grain, and other farming operations where mechanical power is called into play, is another of the many instances where power transmitted by electricity, furnished from a central station, has proven more convenient, more economical and safer than power furnished by a steam engine.

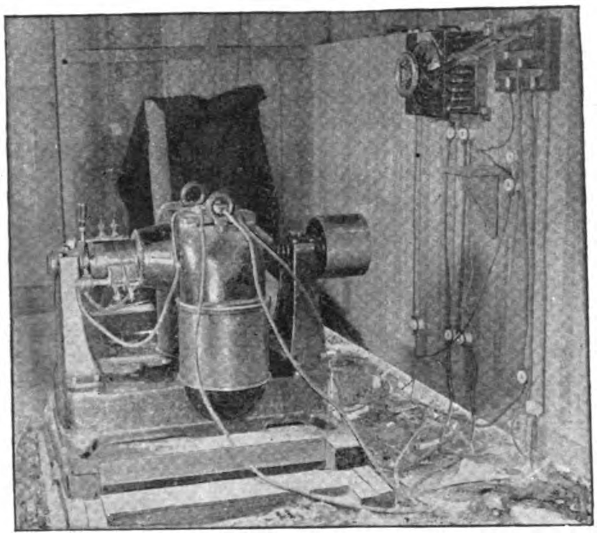

FIG. 1.—MOTOR FOR DRIVING FARMING IMPLEMENTS.

The location of the first plant of this kind is on the farm of the Experiment Station of the State Agricultural and Mechanical College of Alabama, at Auburn, Ala. The station is situated about three-quarters of a mile from the college, and is in every respect a typical Southern farm. One of the necessities on a large farm like this is some source of mechanical power for performing the various operations such as ginning and pressing cotton, cutting up feed-stuff, threshing grain, etc. This power has heretofore been supplied by a 15 h. p. engine and boiler, but it was decided some weeks ago to supplant this by the electric motor, which is furnished with current from a generator in the dynamo-room of the college. This generator is a 12-kilowatt compound-wound Edison, 125 volts, and is run by a 35 h. p. Westinghouse Junior engine, furnished with steam from the steam plant which supplies the mechanical and electrical laboratories. There is also a Brush arc dynamo which lights the campus. The motor is a Thomson-Houston shunt-wound 110 volt 10 h. p. and comprises the device for variation of speed. Owing to circumstances, the dynamo that furnishes the college buildings with lights had to be used as a generator, and the low voltage necessitated a greater loss than would otherwise have occurred. This defect it is proposed to remedy this summer by the installation of a 500-volt system. The generator and motor plants were installed, the poles put up and the wires strung by the students in electrical engineering. A No. 0000 B. & S. wire is used for the outgoing; a No. 6, grounded at each end and at intervals, completes the return.

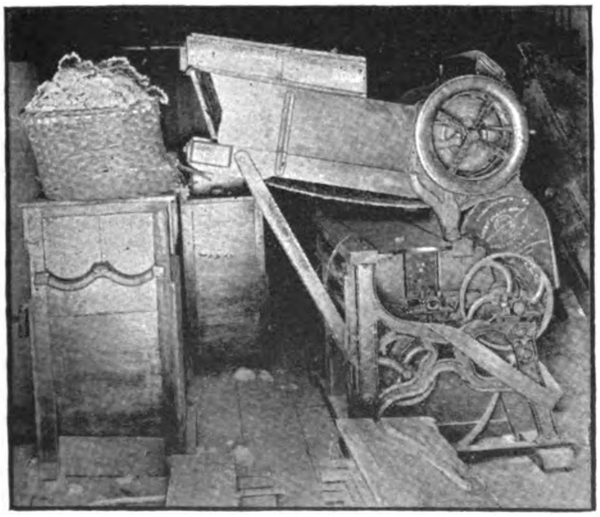

FIG. 2.—COTTON GIN DRIVEN BY ELECTRIC MOTOR.

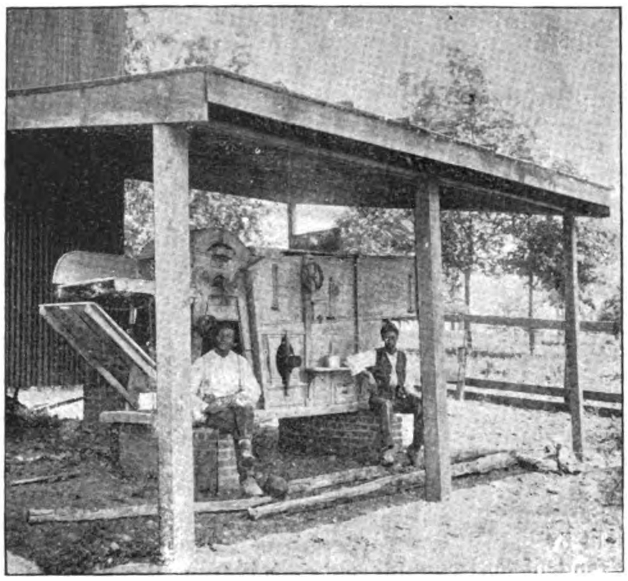

FIG. 3.—THRESHER DRIVEN BY ELECTRIC MOTOR.

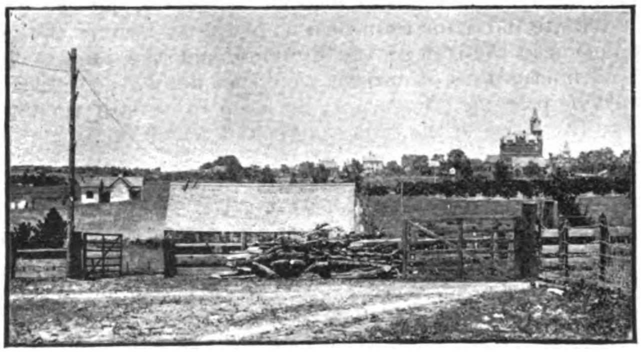

FIG. 4.—LINE AND MOTOR PLANT, AGRICULTURAL STATION, AUBURN, ALA.

The motor, Fig. 1, is belted to a countershaft and from this a belt runs to the feed cutter, gin, screw press, cotton seed crusher and thresher. The feed cutter is used for grinding up oats, ears of corn, shelled corn, peas and all kinds of grain.

In the same room is located the cotton seed crusher. The cotton gin, Fig. 2, and thresher, Fig. 3, are run also from the same countershaft. The silo cutter is used for preparing silo. There is also a corn sheller and separator. Fig. 4 shows a view of the line, the college appearing in the distance.

The steam plant is in operation the greater part of the day, so there is no delay in starting the motor at any time.

The advantages of this plant over the superseded one are its safety from danger to life and property, its safety from damage by fire, its convenience, its economy, its neatness and the advantages necessarily accompanying the centralization of small units into one large plant.

The plant is running successfully and has proven its claims.

THE MAGNETIC EXPLORING COIL.

BY

H. M. Stine

TELEPHONE lines near wires carrying alternating currents, yield by induction a tone in the receiver whose pitch is dependent on the number of alternations. This, although a great annoyance to users of the telephone, has something in its favor—one accustomed to the alternating dynamo may detect a lack of magnetic or electrical balance in the field or armature if, in addition to the fundamental tone, a throbbing, or what may be called "beats," can be heard. These are well-known facts; but that a direct current, especially that used for arc lighting may produce analogous phenomena, is perhaps not so generally recognized. When a dynamo is running we may observe a few details regarding its performance, but after taking note of the current and the potential we must take its magnetic condition largely on faith, and be satisfied with a few inferences. The watt indicator enables us to follow the operation of the steam engine through the varying conditions resulting from changes of load and pressure, but we have no definite indicator to inform us of the molecular changes going on in the iron of the dynamo and the minute and rapid fluctuations of current which we know, theoretically, must be present. Then, too, we seem to be still in doubt as to the cause of the humming sound which is so marked in some dynamos.

The writer has recently made a series of tests with a simple piece of apparatus which yielded results that were not only interesting, but seemed to have an important bearing on the facts just noted. The apparatus employed was an induction coil with the usual bundle of iron wires for the core, and the coil connected to a Bell telephone receiver. In subsequent tests the induction coil of a transmitter was employed and answered the purpose admirably. When the coil was brought near the pole of a dynamo, which, owing to an insufficient amount of iron in its frame, had always shown a large amount of magnetic leakage, a loud musical note was heard, which corresponded in pitch to the annoying humming sound usually emitted by the machine. This entirely agreed with the usual behavior of the machine. When the commutator bars became worn and slightly rounded, this humming was most pronounced. A part of the noise was then doubtless due to the vibration of the brushes themselves, but from the fact that the tone heard in the receiver has been more marked at such times, one is almost forced to the conclusion that the humming is in the iron of the machine, since in this case the variations in current strength would be very marked on the passage of the rounded segments under the brushes.

When the coil was held at the air gap in the field the note was painfully loud, and the intensity of the sound increased perceptibly when it was brought near some bolt heads on the poles, or the edges of the pole-pieces themselves, the best effect being obtained in each case, as a matter of course, when the axis of the coil lay in the lines of force. When the series coil of this compound-wound dynamo was tested the same tone was distinctly heard. By theoretical considerations it is known that the current yielded by a commutated dynamo is not continuous, but intermittent, yet few electricians have ever noted an actual demonstration of this fact. It may be shown by a series of mirrors, as in the case of alternating currents, but here we have an audible effect clearly caused by these pulsations.

The fact that the same tone is produced by the pole-pieces, and in fact by any portion of the frame in the magnetic circuit, shows that there is a constant magnetic flux in the field corresponding to the variations in the current. We would be led to infer this, too, from the usual action of the telephone; but from these facts we reach the conclusion that the strength of field in any dynamo is simply a mean value of these rapidly recurring fluxes.

A Thomson-Houston continuous current dynamo of the "motor type" was also tested and very little external leakage could be detected. A local short-circuiting of lines of force was, however, noted in the lower portions of both shunt coils. As in this type of dynamos, there is considerable latitude to the adjustment of the brushes between non-sparking points; the person in charge of this particular dynamo has experienced some difficulty in adjusting the brushes accurately to the exact point of maximum efficiency. The coil was held near the series winding, and the correct position of the brushes was readily located with considerable accuracy by the intensity of the note in the receiver. The arc dynamo of the same company yields some very interesting results. The nuts on the ends of the yoke bars produce a louder tone than any other portion of the frame, excepting the sharp edges at its ends. There appears also, to be a well-defined line of leakage extending from the lower portion of the negative end of the frame to the upper part of the positive end. If the coil is moved around the commutator the position for maximum efficiency for the brushes is clearly indicated. It is also shown that there is a deformation of the external field surrounding the winding, corresponding to the forward shifting of the magnetic axis by the rotation of the armature. Each dynamo can be shown to possess an individual tone or pitch. In the 50-light arc machine this is a deep bass, while in the smaller dynamos it is much higher, owing to greater armature speed.

Besides being able to indicate proper working conditions, the coil may be used to point out other defects than those noted above. A lack of magnetic or mechanical balance in the armature core, or electrical balance in the coils, or a bad contact on some segment, would each produce its appropriate tone, readily to be distinguished from the fundamental tone of the dynamo itself. This same device could be used to determine the condition of arc lamps on any circuit. If they were in good working order their adjustment would occasion but slight variation in the intensity of the current tone.

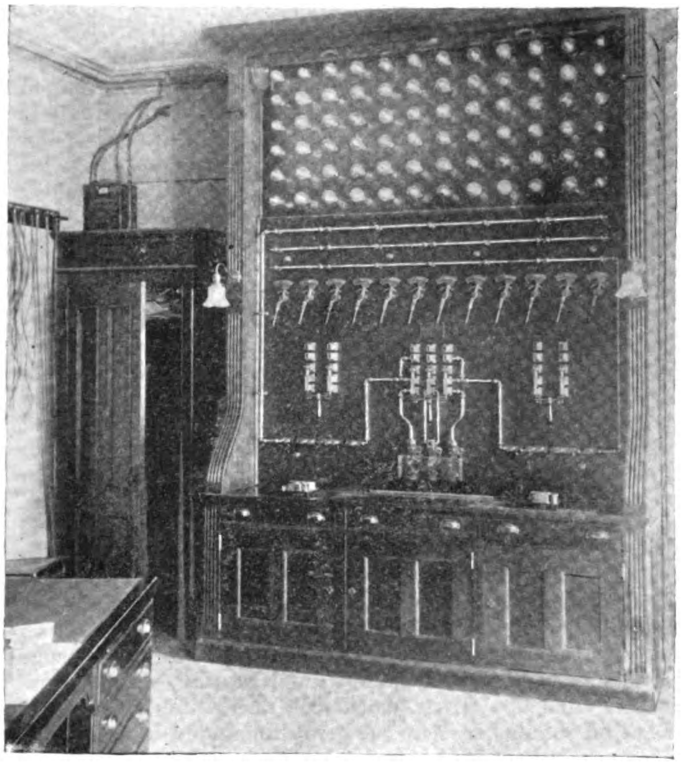
PREVENTION OF SPARKING IN DYNAMOS.

AN ingenious arrangement for preventing sparking between brushes and commutators has recently been devised by M. Deprez. The commutator is made in two parts so placed that the conducting bars and insulating spaces, which are of equal width, alternate with one another in the two halves. The current is collected by two brushes on each side joined by a resistance from the centre of which the main circuit is taken. A battery of accumulators added to this circuit has just sufficient E. M. F. to oppose that of the coil undergoing short-circuit, and thus the inventor is said to have run high pressure machines with absolutely no sparking.

THE TEST BOARD OF THE BOSTON INSPECTION OF WIRES DEPARTMENT.

Soon after the department for the inspection of wires was put on an active footing in May, 1891, Inspector of Wires B. S. Flanders, early seeing the necessity of some reliable means for testing such apparatus as might come before the department, such as the carrying capacity of wires, switches, cut-outs, etc., the testing of insulation, automatic cut-outs and other safety devices, designed and had built by Messrs. J. C. Cushing & Co., electro-machinists of Boston, the test board shown in the accompanying illustration, which through the courtesy of Inspector Flanders, the representative of The Electrical Engineer was able to see in actual operation.

The case stands 11 feet high and is 7 feet 6 inches wide, and is made of highly finished quartered oak. The lower portion is divided into three cupboards for the tanks used in testing the insulation of wires, etc. Just above the doors to these cupboards are two drawers, one on each side of the case, with a blind drawer between them. The roll to this case is said by the manufacturers to be the largest ever made, it being 11 feet long and 6 feet 6 inches wide. In the illustration the roll is thrown up, showing the board ready for use.



Test Board of the Boston Inspection of Wires Department.

On the table to the board are a Weston voltmeter and amperemeter, which can at any time when needed be easily thrown into circuit. The background upon which the bus-rods, switches, etc., are mounted, is a solid piece of slate without a flaw, 6 feet 6 inches wide and 4 feet 10 inches high; above this is a resistance bank of 72 lamps on a polished surface of quartered oak.

The board is wired up to be used for either the 3-wire or 2-wire system. With the large double-throw knife switch thrown down, as shown in the illustration, the current enters the safety catches immediately below the switch, from the Edison 3-wire system, and distributes over the board. With the switch thrown up, the board is fed by the alternating current of the Boston Electric Light Co. which enters through a set of safety catches on the back of the board and then distributes over the board, using the two outsides as the positive pole and the neutral as the negative pole.

The two double-throw switches seen to the right and left of the main switch control respectively the two sides of the board. Immediately below these switches and forming part of the bus-rods are metallic blocks, separated by air spaces, and with screw caps at each end for connecting anything in circuit which it may be necessary to test, and which is thrown into circuit by removing the plug between the blocks. When these switches are both down, as shown in the illustration, the current for the board is evenly divided, part going over the bus-rod running from the right of the switch and part over the left bus-rod. With the left switch up and the right switch down the whole current is fed through the left or top bus-rod; with both switches reversed, that is, with the left switch down, and the right switch up, the whole current passes through the right bus-rod.

The row of twelve switches to be seen just below the bus-rod control the 12 circuits into which the lamps on the board are divided and so that the lights can be thrown into circuit in such manner that the current on the board can be increased gradually until the maximum current or capacity of the board is reached. The wiring in the rear of the board is done with a rubber-covered wire enclosed in conduit tubing. It was wired under the immediate supervision of the inspection of wires department, and is naturally done in the most approved manner. There are connections on the rear of the board by which an auxiliary resistance may be thrown into service, thereby increasing the ampere capacity of the board beyond what the department is ever apt to need. The appearance of the board is very ornamental, and on each side of the front of the case is an ornamental bracket light which adds materially to the appearance of the case when closed.

BREAKING STRAIN OF VARIOUS JOINTS IN HARD-DRAWN COPPER TELEGRAPH WIRES.

BY

Jones

With a view of ascertaining the relative value of joints of different kinds that are used in the United States with hard-drawn copper wires, Mr. M. M. Davis made the subjoined tests at the factory of John A. Roebling's Sons Co., at Trenton, N. J. The samples used in the tests were No. 10 B. and S. gauge, 166 lbs. per mile, with a breaking strength of 520 lbs. The following results were obtained, the description of the joint being given at the head of each table:

Ordinary Twist Joint, 7 turns each side of centre. Soldered.

No. of sample.	Broke at lbs.	No. of sample.	Broke at lbs.
1	485	6	370
2	490	7	460
3	450	8	360
4	430	9	450
5	440	10	380

McIntyre Sleeve, 4½ inches, 3 full twists. Not soldered.

Copper wire is taken at 520 lbs. breaking strain for comparison in "Average per cent." column.

RELATIVE PROPORTIONS IN RAILWAY POWER PLANTS.

BY

D. D. Book.

The very interesting paper by Mr. W. Lee Church in The Electrical Engineer of April 27, on the relative boiler, engine and generator capacities for railway work brings up a matter of great immediate interest, and one which has not been discussed heretofore.

The most difficult question of the three to settle is the capacity of the engine. This will be largely determined by the type adopted, and any general rule will only hold good for one particular class. Mr. Church, of course, appreciates this point, and in his last paragraph says that his remarks apply only to the particular type of engine under discussion. The fact that this engine is a successful, non-condensing compound, proves it to be of a special and unusual type, and conclusions drawn from its performances would not be applicable to other engines.

The number of horse power to be installed in a railway power house is, I take it, a factor of nearly as much importance as the type of engine. In a small station, where variations in the load occur with the startling rapidity given in Mr. Church's diagram, two desirable features of every steam engine are elevated to the most pre-eminent importance. It must be able to open up its admission valves, follow through a considerable portion of its stroke, and thus "walk away" with the heavy loads imposed upon it; and it must have sufficient mechanical strength to stand these overloads. Since makers have built railway engines strong enough (which was not done at first) the fact that they have been able to meet the first condition has been the keynote to railway success. The two reasons for this are that the engine in a small station, which occasionally runs at a great overload, will have its mean point of cut-off somewhere near the point demanded by economy; and we are required to buy less horse power of engines. These appear in one form or other to the directors about to re-equip a whole road. The fact that no non-condensing compound will carry anything like the proportion of overload of a single cylinder engine obliges us to install a much larger engine of the first type than of the second. This is why Mr. Church puts the line showing the rated capacity of engine so high. This engine would have its mean load too small, and the cylinder condensation would be great, due to the large surface of the cylinder; therefore its economy would not be high; also it would be more expensive than a single cylinder not only on account of the greater horse power, but each horse power costs more for a compound than for a simple engine. All this is aside from the question whether any non-condensing compound can be built to have no drag in the low pressure cylinder at all loads. The only engine for which claims are made on this point is, I believe, the one made by Mr. Church. There is a case in point in a small station in Brooklyn, N. Y., where one high pressure tandem engine usually sufficed to carry the load. At instants of light load, the drag in the low pressure cylinder was so great that it was disconnected, and the engine run as a single cylinder.

When we come to large stations of, say, 800 and over amperes output, selection of the engine capacity is much simpler. I recently watched the ammeter of a station of this size for about three-quarters of an hour in the busiest part of the day. The highest reading was 900, and the lowest 400, but this last reading occurred but once, and that only for a short time. There was not a rapid fluctuation of load at any time. Any good single cylinder engine or multiple expansion condensing engine is likely to give satisfaction when working on the steady loads of large stations. Let the horse power required for mean load be the rating of the engines, rated on the rule of the Institution of Mechanical Engineers. This rule gives an engine n h. p. when it is capable of carrying a load of $n + \frac{1}{3} n$ h. p.

Mr. Church must know of some remarkably fine boiler when he advises making the boiler capacity equal to the mean load. The man who would put in any boiler with which I am familiar on this basis would have unending trouble from the hour of starting to the time of getting more boilers. There is a typical case of this, not far from New York, where the mean load in the afternoons is almost exactly 700 h. p. The boiler capacity is just 700 h. p. The result is that every boiler is in use, and being fired in Mississippi River racing style. The horror with which the firemen regard a slight drop in pressure is only equaled by the gravity of the situation. Should the pressure drop, more pounds of steam are required to do the same work; and this the boilers cannot supply unless they have ample reserve capacity. In the case mentioned, two new boilers are on their way to the station.

Probably most electrical engineers will agree with me in the statement that a generator should not be compelled to stand 75 per cent. of overload, as would be the case if we were to follow Mr. Church's advice. Had observations been taken a longer time, it is certain that we would soon find a current much greater than the maximum in the figure. The maximum would without doubt give an overload of 100 per cent. But let us stick to 75 per cent.; also let us assume that we would not have an eye to a future increase of business in designing our plant. This 75 per cent. overload would risk throwing off the belt, bad sparking, and blowing the fuse or magnetic cut-out. It would also decrease the efficiency and nothing would be gained except the difference in cost between this generator and one of proper size. The objections urged against prodigality in engine capacity do not hold for the dynamo. The dynamo has a good efficiency from loads considerably above its capacity down to 10 per cent. of full load. Also, as an increase in horse power does not nearly bring a corresponding increase in cost, we are justified in buying dynamos of ample capacity. As a case in point, I remember seeing the cut-out act three times in as many minutes on a road of medium size. This is a great nuisance, and is bad practice.

To sum up with reference only to the small road under discussion: Rate the capacity of the generator at 128 amperes (the present capacity of the engine). Rate the capacity of the boiler at 96 amperes (a trifle below the present generator capacity). And rate the capacity of the single cylinder engine at the mean load of 64 amperes (the present boiler capacity). The engine to be rated at the horse power given at one-fifth cut-off. Add a certain percentage to these quantities, depending on local conditions for increase of business. The result, I believe, would be satisfactory to every one from the president down to the fireman.

MR. EDISON HONORED.

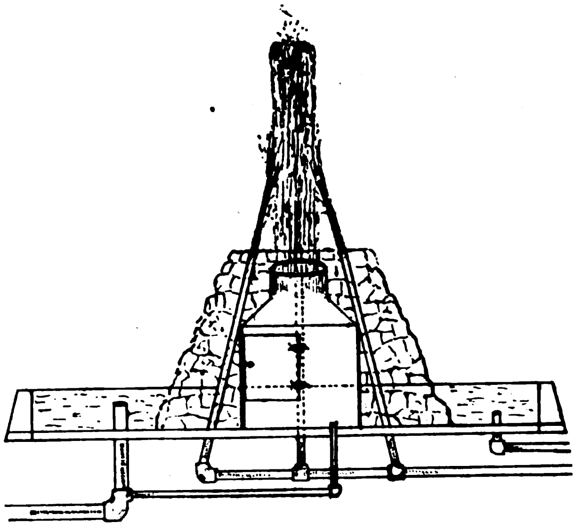
The London Society of Arts prize, consisting of a medal, the prize having been founded in memory of the Prince Consort, has been awarded to Thomas A. Edison. The medal has previously been awarded to Faraday, de Lesseps, and most of the other great scientists.

AN ELECTRIC FOUNTAIN AT WASHINGTON, D. C.

A most attractive novelty in the shape of an electric fountain is now being constructed at Bethesda Park, a suburban pleasure resort near Washington, D. C.

The basin is constructed of broken stone and cement, enclosed by a wall two feet high, the entire structure being lined inside and out with Portland cement. In the centre of this basin is a vault 6 feet square and 6 feet high with an entrance in the side. The vault is covered with a rustic pile of rocks, and gives the appearance of a rocky mound, in the centre of which three streams of water rise at equi-distant points from each other around a skylight in the roof of the vault. Overflow, feed and return water pipes are supplied as may be seen in the accompanying sketch.

In the centre of the vault is located an electric projector of 5,000 candles; by means of a reflector, double-convex lenses and mirror, all of this enormous volume of light is concentrated and thrown up through the skylight of the vault in a perpendicular column, 24 inches in diameter. Between the mirror and the sky-light, pivoted on one side of the same is a wheel carrying colored lenses, viz., red, green, blue, yellow and white, which rotates slowly by an individual $\frac{1}{3}$ h. p. motor, giving the column of light a complete change of color every thirteen seconds.



Electric Fountain at Washington, D. C.

The three columns of water rising as they do at equidistant points around the centre, are inclined at such an angle that at a height of 40 feet they would unite in one column, break and fall in broken streams down again. The column of light, rising in the centre of the three streams, brilliantly colors the whole exterior as well as the interior, viewed from whatever side according to the color thrown over the lens, until it strikes the point where the three columns unite and break, where the light also breaks; and as the water turns to descend the light is reflected in every direction, making a magnificent effect, which can only be likened to a volcano in full operation throwing out a continuous stream of molten lava of constantly changing color.

The water for this fountain is supplied from a 6,000-gallon tank, through a Gould's "Triplex" pump, operated by a 5 h. p. Excelsior motor, delivering 80 gallons of water 40 feet in the air every minute. The electrical projector is of the New American Electrical Arc Light Co.'s pattern, and a C. & C. motor operates the color machine.

The complete cost of this fountain is about $4,000; it was designed by Mr. L. D. Bliss, electrical expert of the installing firm, Messrs. Congdon, Bliss & Daniels, of Washington, D. C.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JUNE 1, 1892. No. 213.

In the establishment of a principle, it is of the first importance that all probable suggestions relative to it may be subjected to critical examination and tried by the test, as far as possible, of experience; it is in this way that science is advanced.—Joseph Henry.

THE ECONOMY OF CONDENSING ENGINES.

STEAM engineering has now come to play such a prominent part in the engineering work of electric central stations that discussions relating to this branch of the equipment have been given full scope in our columns, and the latest has, we hope, resulted in a clearer understanding of the question involved. That the economy of a central station, other things being equal, will in general be higher when condensing engines are used is now generally recognized. But there is a phase of this question which is now presenting itself for the consideration of central station managers, and which deserves more attention than appears to be devoted to it at present. The position is well put in the article by Mr. I. H. Babcock, in this issue. He asks the very pertinent question whether, in brief, it pays better to use the exhaust steam for condensing purposes or to distribute it to customers for heating purposes. The problem is one which can, we believe, be figured out without much difficulty in each particular case. The concrete example which is given by Mr. W. F. Collins on another page, of such a plant at Springfield, Ill., goes far towards showing that the position maintained by Mr. Babcock is a tenable one. The question simply resolves itself into striking a balance between the saving in fuel effected by condensing and the income derived from the sale of the exhaust steam after deducting the expense incurred for the distributing plant. Where stations are situated in proximity to thickly settled districts, as in most cases at present they are, and are maintained in operation during twenty-four hours of the day, the advisability of investigating this method of increasing the returns from central stations needs no further pointing out. Indeed it may not be generally known that one of the largest central station companies in this country now seriously contemplates the turning over, as it were, of its exhaust steam to a separate company, organized solely for the purpose of distributing this product for heating and other purposes. With these examples before us it is not difficult to discern in what direction the work of the electric central station of the future may be carried. As we have often pointed out, central stations operated on a business basis are not established to promote a special method of manufacturing current, but by carrying on a business in light, heat and power with any and every form of current, to earn dividends. If incidental to the sale of current, a profitable business can be done in the sale of exhaust steam, it behooves every local company to look into the subject for itself very thoroughly.

WHAT ELECTRICITY IS.

UNDER the above caption we took occasion in our issue of May 18 to express some doubts as to the sufficiency of the experiments undertaken by Doctor W. W. Jacques to warrant the conclusion arrived at by him that the electric current is a bodily forward movement of the ether. Our remarks, we may state, were called forth by the perusal of a pamphlet issued by the American Academy of Arts and Sciences, before whom Doctor Jacques delivered his address. The pamphlet contained merely that, so that we were entirely unwitting of the discussion which followed and which Mr. Berthold says was participated in by some of our "leading mathematical electricians." Nothwithstanding this, our original opinion remains unchanged in so far as regards both the sufficiency of Dr. Jacques's experiments and the validity of his conclusions. We are perfectly willing, however, to accord to Dr. Jacques the credit due him for having conceived this method of utilizing the enormous velocity of the earth as a means for carrying out the experiments only hinted at by Clerk-Maxwell. Mr. Berthold's note on this subject will be found in our pages this week.

THE BREAKING STRAIN OF WIRE JOINTS.

IT is an axiom in mechanical designing that the strength of any structure is that of its weakest member, and the application of this rule to electrical work is eminently exemplified in the construction of overhead electrical conductors. Joints are of necessity of frequent occurrence, and hence it becomes all the more important to take special care in order to avoid any weakening of the lines at such points. Beginning with the early days of the telegraph this was well recognized, and from that time until the present not a little thought has been given to the devising of joints in line wires, with the result that a variety have come in more or less general use. With a view of obtaining independent and reliable information as to the merits of these different types, Mr. Francis W. Jones, electrician of the Postal Telegraph Co., confided to Mr. M. M. Davis the testing of a number of joints, and the results of these tests are given elsewhere in this issue. They show that in this detail, as in all others in electrical work, care and attention are necessary in order to secure the best results. Some of the joints in common use, like the ordinary unsoldered twist joint, proved to be little more than half the strength of the remaining part of the wire, while on the other hand the Britannia joint gives nearly the full strength of the wire. It should be pointed out, however, that these tests show merely the character of the various joints as related to hard-drawn copper wires, and that in all probability the ratio of breaking strain would vary for different material, as hard-drawn copper wire exhibits peculiarities which are not possessed by iron or steel, or indeed by soft copper.

ELECTRICITY BUILDING AND THE EXHIBITORS.

A CIRCULAR about to be issued by Prof. John P. Barrett, chief of the Electrical Department of the World's Fair, states that there will be, according to the latest plans, 500 h. p. for the operation of motors in Electricity Building, 500 h. p. for arc lights, 500 h. p. for incandescents, and a reserve of 500 h. p. for extra service. All the generating of current is to be done in what is known as the general power plant, all the generators being installed at that point, adjacent to steam power of like capacity, and thence the circuits will run through a subway to the Building. Fireproof vaults will also be provided for transformers. The Building will be divided up into sections, and each section will be allotted to an exhibitor, who will have to install his own generator, belting, cable, wires, lamps, motors, etc., according to the service undertaken, as well as pay the pro rata of the costs incident to the erection of machinery. It is also intended to make a charge to exhibitors who want special light and power but do not come in under the above provisions. The object of this is, that the Building may not be a source of expense to the Exposition Management. If these plans be carried out fairly and justly, there should be no ground for complaint in any quarter.

CENTRAL STATION PROPORTIONS.

ALTHOUGH the importance of maintaining certain proportions between the boiler, engine and dynamo capacity in railway power stations was recognized even in the early days of electric railroading, the lapse of time has only further emphasized the necessity of carefully considering these factors in designing central stations. In discussing this subject in a recent issue, Mr. W. Lee Church argued very ably that with a given maximum power called for, boilers and dynamos could be installed considerably below the maximum capacity demanded at any one time, owing to the capacity of these elements for maintaining considerable overload for short periods of time. Two engineers in our columns this week take issue with Mr. Church, and point out difficulties which are likely to arise in a station which is not liberally equipped to sustain a heavy overload for a considerable length of time. Such conditions frequently arise in electric railway practice and hence should be provided for, they say. It seems to us that one of the elements in this important question is the manner in which the station and road are run. Meantime, Mr. Church's rejoinder to these criticisms will be eagerly looked for.

LIGHTING THE WORLD'S FAIR.

ONE of the most extraordinary of recent electric lighting episodes appears to have come to an end—though, perhaps, it is hardly safe yet to say that an end has been reached, for should Mr. Westinghouse decline to furnish a bond for $1,000,000, the contract for incandescent lights for the Chicago World's Fair will still be open. It is now stated that after all the hurly-burly of the past month, Mr. Westinghouse has been awarded the contract for 92,622 lamps, on the alternating system, at $4.25 per lamp, or $393,643 in all. Perhaps Mr. Westinghouse can figure out some profit in this, but we are afraid that he must look for his return very largely in the advertising that will come from the fact that the Westinghouse Company is doing the work. Possibly, as we have suggested, Mr. Westinghouse may not care to put up so large a bond, and the amount does seem rather heavy, but he is not the kind of man to stop short after having gone so far.

The Telephone as a Galvanoscope.

THE use of the telephone as a galvanoscope, especially when employed in connection with portable testing apparatus, though often pointed out, has frequently met with unsatisfactory results owing to the fact that the complete silence which would indicate a balance in the Wheatstone bridge can rarely be obtained. The reasons for this are very clearly pointed out by Prof. Brown Ayres in another column. He shows that when employing a circuit breaker we are not dealing with a simple harmonic current variation but with a complex one, so that if a balance be obtained for one component there are others still which would give indication of their presence in the telephone. The remedy for this is pointed out, but unfortunately cannot be generally applied in practice. The employment of the telephone in a somewhat analogous manner for the study of the distribution of magnetism in dynamo-electric machines is also treated, by Prof. W. M. Stine, in this issue, describing how the telephone may be put to very practical use, not only in finding the best working condition of the machine itself, but also that of the arc lamp circuit.

Lord Kelvin on "Kelvins."

IT appears that Lord Kelvin is not particularly "stuck" on the use of his new title as the name for the Board of Trade unit, and that as a matter of fact a new name will not be introduced, owing to his criticism of it during the earlier stages of its adoption by the Board. This should be a great relief to our witty correspondent, Dr. Park Benjamin, who cannot get over the fact that Sir William Thomson has been willing to accept a peerage, nor forgive Mr. Lockwood for his complacent acquiescence in the state of things that allows a distinguished scientist to become a baron. We must say, for ourselves, that the only saving grace of such a system as the English peerage and "beerage" is seen when the honor—for it *is* an honor in England—is conferred on such men as Tennyson and Thomson.

PRELIMINARY NOTE ON SOME TESTS OF THE CARHART-CLARK STANDARD CELLS.

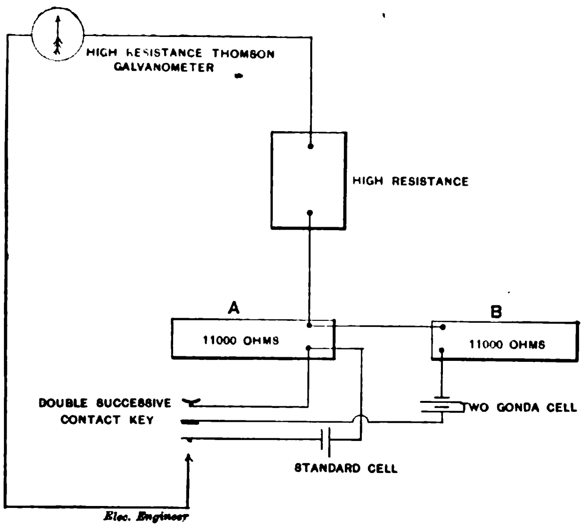
BY

Percy. Matthews & James E. Ives.

Johns Hopkins University.

The following tests were made to determine the relative variation of E. M. F. between individual cells and of the E. M. F. of a given cell with temperature. Six cells were sent to us directly by Professor H. S. Carhart, precisely the same as those supplied by him to Messrs. Queen & Co. They were received on February 14, and first tested March 12.

The arrangements for the test are shown by the following diagram:



METHOD OF TESTING STANDARD CELLS.

These will be seen to be the same as in the method used by Lord Rayleigh and Mrs. Sidgwick in their test of the Clark standard cells. The total resistance used in the two boxes A and B was 20,000 ohms. The ohms in A required to balance a cell are obviously proportional to its E. M. F.

The following are the results of our first test, Table I:

TABLE I.

No. of cell.	Temperature of cell in deg. C.	Ohms in A to balance.	Ohms in A to balance at 15° C.
227	22.3	10,666	10,696
228	23.8	10,660	10,697
229	23.2	10,664	10,698
230	23.2	10,664	10,698
231	24.2	10,662	10,700
232	22.9	10,663	10,696

The ohms to balance at 15° C. are deduced by means of the formula given by Prof. Carhart, viz.:

$$E_t = E_{15^\circ}\,[1—.00039\,(t^\circ—15^\circ)].$$

The cells were next immersed in a water bath in order to compare the E. M. F. more nearly independent of temperature. The following results were obtained in this way, Table II:

Cell No. 230, which, it will be seen, has the lowest E. M. F., had two days previously been placed on a short circuit of 15,000 ohms. On account of the proximity of the water and the very high internal resistance of these cells it is possible that the terminal P. D. was reduced, due to leakage, by something of the order of 1 in 10,000.

TABLE II.

No. of cell.	Temperature of cell in deg. C.	Ohms in A to balance.	Ohms in A to balance at 15° C.
227	13.2	10,647	10,640
228	13.3	10,644	10,637
229	13.2	10,646	10,638
230	13.2	10,643	10,636
231	13.1	10,646	10,639
232	13.2	10,644	10,637

From these tests, therefore, all that can be fairly concluded is that the variation of the six cells between themselves is not greater than 4 in 10,000, and that from the mean the variation is not greater than 2 in 10,000.

The cells were then tested for the accuracy of the temperature coefficient given by Professor Carhart in the following way: Cell No. 229 was immersed in a water bath with a thermometer alongside of it, and balanced at different temperatures. The temperature of the water was varied and the water stirred. In order to check the "Gonda" cells for any change in their E. M. F. during the time of the experiment a Carhart-Clark cell, set up in its brass case with a thermometer in the hole provided for that purpose, was balanced against the Gonda cells.

TABLE III.

Ohms to balance cell at const. temp. at 15° C.	Temperature of cell under test in deg. C.	Corrected ohms to balance cell under test. Observed.	Ohms to balance from coefficient .00039. Calculated.	Difference in parts in 10,000.	
10,582	11.6	10,618	10,615	2	Cell No. 229.
10,580	15.2	10,600	10,600	0	
10,581	19.1	10,584	10,584	0	
10,580	24.2	10,562	10,563	1	
10,579	28.2	10,546	10,546	0	
10,578	37.6	10,509	10,507	2	
10,575	29.6	10,548	10,541	2	
10,575	24.6	10,562	10,561	1	
10,575	20.0	10,582	10,580	2	
10,572	14.9	10,603	10,601	2	
10,571	9.5	10,625	10,624	1	
10,573	7.7	10,628	10,631	3	
10,600	10.7	10,612	10,612	0	Cell No. 228.
10,600	20.6	10,575	10,571	4	
10,600	24.2	10,557	10,556	1	
10,599	30.7	10,526	10,529	3	
10,598	40.1	10,491	10,491	0	
10,608	50.8	10,449	10,445	4	
10,599	41.6	10,479	10,484	5	
10,598	31.4	10,525	10,526	1	
10,598	25 2	10,552	10,552	0	
10,598	14.8	10,591	10,595	4	
10,598	4.4	10,638	10,638	0	

In Table III the column to the left indicates the change in E. M. F. of the Gonda-Lechanché cells, for which the ohms to balance in the next column but one are corrected. This cell was not one of the lot sent to be tested.

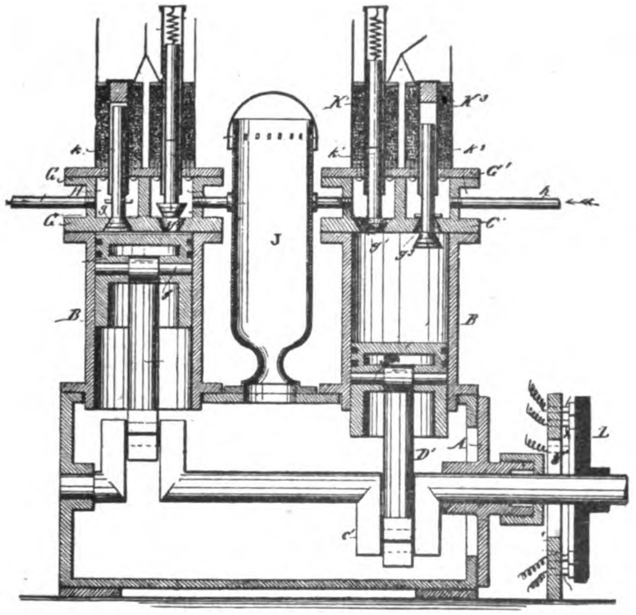
The first set of the above readings was taken on cell No. 229; the second on cell No. 228. We place more reliance on the first test as the temperature was varied more slowly. The only difference in the arrangements for the two tests was that in the second case the cell used to check the Gonda cells was immersed in another water bath with a thermometer. The temperature of this cell varied 2° C. in six hours.

THE DITTMAR AND FALKENHAUSEN VACUUM PUMP.

With the recent tremendous growth of the electrical business and the manufacture of incandescent lamps in particular, inventive genius has ever been busy devising new schemes and apparatus for facilitating and cheapening the process of manufacture. As the exhausting of the lamps is probably the most exacting detail of their manufacture any improvement in apparatus for this purpose cannot fail to be of interest.

The accompanying illustration shows a sectional view of an electro-mechanical vacuum pump devised by Messrs. A. A. Dittmar and H. F. Falkenhausen, of this city. As will be seen, two cylinders, B B′, 6 inches in diameter, are mounted vertically upon a crank chamber, the pistons being connected to the two opposite cranks by short connecting rods, and the cylinders closed by tight fitting casings G G′ at their upper ends.

These casings are divided into two compartments, each carrying a solenoid, as K K′, tightly screwed down, with an oil groove surrounding it. The inside compartments connect by a discharge pipe with the trap pipe J mounted upon the crank chamber, while the outside compartments connect with the vessel H H, to be exhausted. The crank chamber, cylinders and trap are completely filled with oil, which is allowed to stand about two inches higher than the top of the cylinder.



The Dittmar and Falkenhausen Vacuum Pump.

The main feature of this pump is the valve mechanism. Two valves such as $g\,g^2$ are seated in each compartment, one tapering upward and the other downward. Each valve stem forms the core of a solenoid excited by a current from any source, and controlled by a commutator L which is carried on the crank shaft between the pulley and the crank chamber. The commutator consists of two half rings each covering a different part of the periphery, and fed simultaneously by a brush pressing against it. Two other brushes press against the cut sections of the commutator and feed the solenoids.

The action of this arrangement will be easily understood. As the piston has just reached its highest point, and starts on its downward course, one of the brushes at the commutator comes into contact with the section connected to the wire leading to the solenoid. This solenoid, which operates the discharge valve g^2 draws the core up and holds it there until the brush leaves its section of the commutator, which will take place the moment the piston starts on its upward course, when it will be released to allow the air or gases drawn down from the lamps or vessel, to be exhausted. At the moment the piston rises, the exhaust valve is closed by the section of the commutator coming in contact with the solenoid operating it and remains in this position up to the moment the piston starts on its downward course, when the current is interrupted, the exhaust valve g opened, the discharge valve g^2 closed and the operation is complete. The action is entirely automatic. Many efforts have been made to construct a mechanical pump, to displace the mercury pump, but owing to the use of stuffing boxes necessary to operate the valve mechanism, more or less leakage has always taken place. In this pump these obstacles are claimed to have been overcome by the use of the solenoids. By the avoidance of stuffing boxes the inventors of this new pump claim to have overcome all the difficulties heretofore encountered in the use of mechanical vacuum pumps.

We have recently had occasion to see the pump described above in actual operation and on a test it was shown that after leaving this pump, the air remaining in an ordinary 16 c. p. lamp bulb was no greater in volume than a pin head. The pump which, on account of its simplicity, is exceedingly cheap to manufacture is being exploited by Messrs. A. L. and C. F. Reinmann, gentlemen whose names are well known in connection with incandescent lamp manufacture in this country.

MEASUREMENT OF RESISTANCES BY ALTERNATING CURRENTS.

BY

Brown Ayres

The use of the telephone as an exceedingly sensitive galvanoscope in the Wheatstone bridge occurred naturally to many soon after the invention of the instrument. The possibility of such use was pointed out by myself,[1] among others, as early as 1877. The method has since been used by Kohlrausch and is known as Kohlrausch's method. Its special fitness for the determination of electrolytic resistances has made it useful in his hands. Its use for determinations of resistances of ordinary conductors has frequently been attempted, but as a rule is not satisfactory. The reason for its failure to give good results is not difficult to see. The oscillatory or pulsatory current produced by any form of circuit breaker is not a simple harmonic in character, but, broadly speaking, is of a character analogous to the air vibrations from a reed pipe—having a fundamental and harmonics.

When we attempt to balance a bridge in which a telephone is the indicating instrument, we find it impossible, as a general rule, to find any point of complete silence in the telephone. The cause of this is that the impedance for all the pulsations making up the complex current according to the principle of Fourier is not the same. If

$$I = \sqrt{R^2 + p^2 L^2}$$

where I is the impedance, R the conductor resistance, L the coefficient of self-induction and $p = 2\,\pi\,n$, n being the number of oscillations per second,—it is evident that for a real resistance balance we will still have an effect due to the term $p^2\,L^2$. The only way therefore to get silence in the telephone is either to have $L = 0$, or $p = 0$; that is, to have the resistances to be compared wound anti-inductively, or to use a steady current.

If we attempt to measure the resistance of a circuit having inductance, when we have balanced for the impedance of any harmonic the balance will not be perfect for the others. Hence a sound of somewhat different character will be heard in the telephone. For the measurement of liquids in tubes or short wires of small inductance the method can be used; but for ordinary purposes it is not satisfactory. If we could get a simple harmonic current, we could get a balance; but even then it would be the ratio of impedances that we had found, not the ratio of resistances.

BRAKING STREET CARS ELECTRICALLY.

BY

Maurice Hooper

I HAVE read in THE ELECTRICAL ENGINEER of May 11 a description of a method of braking electric railway cars devised by Prof. S. H. Short. This speaks of an arrangement such that one motor overpowers the other, and, as I understand it, one motor, acting as a generator, tends to drive the other as a motor, and thus retards the car.

I am not familiar with the Short car wiring, but understand that the two series-wound motors are in parallel, having a separate reversing switch for each armature. With this method of wiring, where the armatures are not parallel independently from the fields, considering the car coasting down hill with the reversing switches set for a direction opposite to that of the car, is not the case that of two series dynamos in parallel and driven at equal speeds? In this case the machine building up first would reverse the other, and then the two would run as two series machines wired in series on short circuit, and would generate a tremendous current and reduce the speed of the car to a point where the resistance to the motion of the armature in the field balances the attraction of gravity, or other force propelling the car. With this, considering a car wired as I have assumed the Short cars are, it would be necessary only to reverse the car, when coasting down hill, to slacken its speed without the use of current from the line, or of brakes.

I have had a car on the West Chester, Pa., street railway equipped, for some time, with a switch on each platform to disconnect the trolley end of the car wiring from the trolley and connect it to the car ground. By doing this, and throwing the controlling switch as though to reverse the car, the car may be controlled on a down grade very easily. The motors build up rapidly and bring the car up rather abruptly, but not sufficiently so to endanger the gears, and not anything like the way it is done on reversing the motors, even when the latter is done through maximum resistance.

In the case of the Edison equipment, with the motors short-circuited, it is a case of two shunt dynamos connected in parallel, and having fields of such low resistance that they practically short-circuit the armatures. This arrangement of wiring, while it takes the place of a set of reserve brakes, costs but a few dollars to apply to a car. It requires a single-pole double-throw switch on each platform, with the lever connected to the "A" of the wiring and one point connected to the trolley and the other to ground. This switch takes the place of the ordinary cut-out switch.

While this method of braking is not to be recommended for ordinary use, as is no method that uses the gears, it has certain very decided advantages over any other. It is well known that where there is any tendency of the wheels to slide on the rails the best braking is that which comes nearest to making the wheels slide without doing so. The motors accomplish this automatically, as the instant the wheels slip the armatures cease revolving and there is no further tendency towards retardation. This is an especially valuable feature and makes it possible to descend safely, without sand, many grades that are otherwise extremely dangerous.

As we use the switch the motormen are not allowed to brake the car with it, except in case of absolute necessity. It should be tried at least once each day to see that it is in order. This may be done when the car is running at such a low speed as to bring very little strain on the gears. I have never known the method to fail and think it saves the second set of brakes on a car, which means that it saves money in first cost and in maintenance, as well as the inconvenience of the extra brake rods and other mechanism about the truck and platforms. The only surprising thing in connection with it is the fact that it has not come into common use before this.

STORAGE BATTERIES IN RAILWAY POWER STATIONS.

BY

W. M. Miner

"WHY not try it here?" are the concluding words of your recent editorial on storage batteries in central station work abroad. Yes, why not, and particularly in connection with electric railroads? Mr. W. Lee Church's excellent article in the same issue of the ENGINEER, on the requirements of the generating station of an electrical street road, shows clearly what a strain this important part of the plant is subjected to, on account of the rapid and extreme fluctuations of the current.

By the use of a storage battery of sufficient ampere capacity, in shunt with the generator we could use an engine and generator, whose rated capacity would be a little above the average requirements of the station, thereby working our engine at its greatest efficiency, and preventing those sudden changes from no work to more than the engine and generator were calculated to stand. When the demand of the feeder lines is *less* than the average output, then it goes to the storage battery; and when the demand is *more* than the average, the storage battery comes to the aid of the generator, keeping the supply to the feeders nearly constant, merely requiring the generator to work at its full capacity, the storage battery doing the rest. This would improve the running of the cars also, as ordinarily, when this heavy load comes on the generator it affects all the motors working at the time, lowering the potential quite perceptibly. I have seen lights in cars in which I was riding, dim to nearly, or quite, half their candle power, caused by the heavy drain on the line, due to the starting of several cars at about the same time, at other parts of the line. The storage battery would, in such cases, I believe, prevent this large drop in potential. As 500 volts is the usual potential for railway work, it would require about 250 storage cells in series; the space occupied might be considered an objection, but as they could be placed on shelves one above the other, the *floor* space would not be so excessive after all.

It is not my intention in this short article to go into details or figures, but to call the attention of electricians to what seems to me would be a useful adjunct to the generating station of street railways. I have used this method of supplying current to a motor where it was imperative that the motor should run absolutely steady and found it to work well, so that I have every reason to believe it would, in a certain measure, do the same for street car work.

A STUPENDOUS COLUMN OF WATER AT VIRGINIA CITY, NEV.

ALTOGETHER the most extraordinary water-power installation —so far as head is concerned—ever known has recently been made by the Pelton Water Wheel Co. in one of the famous Comstock mines at Virginia City, Nevada. The wheel is 36 in. diameter, made of a solid steel disc with the buckets riveted on to the periphery in a way to afford absolute security, and weighs, complete, 180 lbs.

It is running under a vertical head of 2,100 feet, equal to 911 lbs. pressure; 460 feet of this head is obtained from the pipe line of the Gold Hill Water Co., and the remaining 1,640 feet from the California and Con. Virginia shaft, down which the pipe line is run to the Sutro Tunnel level, where the power station is located and through which the water discharges after passing over the wheel. The wheel runs at 1,150 revolutions, with a peripheral speed of 10,804 feet per minute, or about 120 miles per hour.

The construction of the wheel amply provides for the centrifugal strain the velocity of the water gives it, running without load, when it would attain the enormous speed of 21,608 feet per minute, equal to about 240 miles per hour. A nozzle tip ½ in. diameter gives under above conditions 100 h. p. Every miner's inch of water, equal to a flow of 1.6 cubic feet per minute, gives 5 h. p., while 1 h. p. is given for every 2 lbs. of metal in the wheel. It is only by comparison that an idea can be obtained of the height of a column of water due to such pressure. It is more than four times as high as the Washington Monument and considerably more than twice the height of the Eiffel Tower. It is safe to say that no water wheel has ever before been operated under any such head, nor any such demonstration afforded of the velocity and power of water under such an extreme pressure.

The installation made by the Pelton Company some two years ago in the Chollar shaft on the Comstock lode is in some respects no less extraordinary. This consists of six 40 in. Pelton Wheels, which run under a vertical head of 1,680 feet, driving that number of electrical generators, the power from which is conveyed up the shaft to the Nevada Mill some 2,000 feet distant. These wheels only weigh 220 lbs. each, and with nozzle tips ⅝ of an inch diameter develop 125 h. p. each.

The water is first run over a Pelton wheel on the surface under 460 feet head, and is then carried down the shaft by a pipe to the Sutro Tunnel level, where the underground station is located, the power from the electrical generators being conveyed to the countershaft of the mill with which the surface wheel is connected, the two distinct forces working together in perfect harmony.

A most interesting illustration of the double use of water is here given, some 400 h. p. being produced in this way from what may be termed waste water. This station has now been running more than three years without interruption and practically without expense in the way of repairs, as well as without any appreciable loss of efficiency, affording a most striking example of the advantages of water power, both by direct application and electric transmission, as well as the reliability of such a plant under such extraordinary conditions.

RESISTANCE STANDARDS—THEIR MANUFACTURE AND ADJUSTMENT.[1]

BY ELMER G. WILLYOUNG.

THE standard of resistance, as generally known, is a length of wire of one kind or another, wound upon a spool, mounted in a convenient case to protect it from injury and moisture, and having its resistance at some given temperature definitely determined; a true standard also has its rate of variation of resistance for change of temperature accurately known. Sometimes one coil is mounted up alone and sometimes many coils of different values are put up in the same mounting.

In the manufacture of standards of resistance a great many qualities are required of the resistance wire which shall be used. It should have high specific resistance, and as small a temperature coefficient of resistance as possible; it must not change its resistance in time; it must not be oxidizable by the air or by the medium in which it may be enclosed; and it must be of a hardness suitable for handling in manufacture and adjustment without injury. The requirement of high specific resistance immediately compels us to reject copper, iron, aluminum, silver and all other pure metals except lead, antimony and bismuth. The softness, difficulty of working, and high temperature coefficient, as well as many other reasons, would throw these last three out of the account. The matter of temperature coefficient alone, in fact, would compel us to reject all pure metals since they all increase roughly about twenty-five per cent. in resistance between 0 and 100 C., except iron, which increases about forty per cent. We are, therefore, led to try alloys. Dr. Matthiessen, chairman of the sub-committee (of the Committee on Electrical Standards of the British Association), from 1862–65, having in charge the investigation of the properties of wires with reference to the selection of a suitable one to be used in the standard of resistance, decided upon by the British Association and now known as the B. A. ohm, and examined very exhaustively a large number of wires, among which were pure iron, silver, copper, thallium and other metals, and a great many alloys; he finally concluded that silver alloyed with 33.4 per cent. of platinum was the best alloy obtainable. This alloy, known as platinum silver, is still used by English makers; it has a specific resistance of twenty-four microhms and a per cent. variation per degree C. of $\frac{31}{100}$. In selecting this alloy we see that the requirements of high specific resistance and low temperature coefficient have both been observed, the resistance of platinum silver being about sixteen times that of copper and its temperature coefficient less than $\frac{1}{100}$ that of copper.

With reference to the constancy of resistance in wires it may be well to mention that many metals and alloys seem to alter in electrical resistance with time, or on being subjected to change of temperature. In an investigation carried on by J. Bergmann, a German electrician, in the latter part of 1889, he reports that, after raising to and maintaining at 300° C. for one hour and then cooling, the resistance of several substances changed as follows:

	Per cent.
Copper decreased	2.4
Aluminum "	5.0
Magnesium "	6.8
Zinc "	2.4
German-silver increased	$\frac{2}{10}$

It is almost self-evident that the resistance of a metal or alloy is a function of its density; hence, all causes tending to change the density of the resistance metal will also tend to change its resistance. It is quite reasonable to expect, therefore, that an increase of resistance should be observed after a wire is wound upon a spool. A wire wound upon a spool not over eight times its own diameter will increase from one-half to two per cent. in resistance; a part of this increased resistance is due to the increased hardness caused on the inside of each turn, by the bending stress, and hence gradually falls away as the wire slowly anneals. For this reason, it is unsafe to send out a resistance standard as correct until several months have elapsed after winding.

According to Drs. Feussner and S. Lindeck, in *Zeitschrift für Instrumentenkunde*, February, 1891, an alloy composed of seventy per cent. copper and thirty per cent. manganese had a resistance of about five times that of German silver and a temperature coefficient of but $\frac{4}{1000}$ per cent. per degree Centigrade, while an alloy of seventy-three per cent. copper, three per cent. nickel, and twenty-four per cent. manganese had a specific resistance a little less than three times that of German silver, and a *negative* temperature coefficient of $\frac{3}{1000}$ per cent. Hence we see that it ought to be entirely possible to obtain a wire having a zero coefficient, *i. e.*, not changing resistance at all for change of temperature by properly combining the constituent metals of this alloy.

A strictly standard resistance is, according to the practice of the best makers, adjusted to anything within from $\frac{1}{10}$ to $\frac{1}{100}$ per cent. of absolute accuracy. A *single* coil would not be considered a "standard coil" unless it were accurate within from $_{50}$ to $\frac{1}{100}$ per cent. of absolute accuracy. To obtain this high accuracy of adjustment it is easily seen that very exact methods of measurement must be employed; should we attempt to measure an inch within this limit of error, the error could not be over $\frac{1}{10000}$ inch, an exceedingly small quantity. Various methods have been suggested and employed by different parties at different times. Such an apparatus designed by Prof. Fleeming Jenkin, was used somewhat by the British Association Committee in 1862. A complete description of this method and convenient apparatus will be found on p. 38 of *Reports of Electrical Standards*, published by Spon.

I have here a piece of apparatus first designed several years ago during my student days. It is a modification of an arrangement devised by Prof. S. P. Thompson, and described in *Stewart & Gee*, 2d vol., p. 160. The one I have here was first suggested to me by Prof. H. S. Carhart, of Michigan University, and has since been somewhat modified by myself. If we take an ordinary slide wire bridge having four openings for coils at the back and (the slide wire being in front) fill these spaces, beginning at the left, with coils designated P R_1 R_2 and Q, respectively, connect the battery from between P and R_1 to between R_2 and Q, and the galvanometer from between R_1 and R_2 to a point on the slide wire, we have substantially the method which is known as the Cary-Foster method. Designating the resistance of copper connector at the left by r_1 and of copper connector at the right by r_2 and letting P be the resistance of unit division of the wire.

$$\frac{R_1}{R_2}=\frac{P+r_1+X_1\,\rho}{Q+r_2+(L-X_1)\,\rho} \tag{1}$$

where X is the reading on the bridge wire and L the total number of divisions. Reverse the position of P and Q and we have

$$\frac{R_1}{R_2}=\frac{Q+r+X_2\,\rho}{P+r_2+(L-X_2)\rho} \tag{2}$$

---

[1] Abstract of a paper read before the Electrical Section of the Franklin Institute.

From (1) we have

$$\frac{R_1}{R_1 + R_2} = \frac{P + r_1 + X_1 \rho}{P + Q + r_1 + r_2 + L\rho} \qquad (3)$$

and from (2) we have

$$\frac{R_1}{R_1 + R_2} = \frac{Q + r_1 + X_2 \rho}{P + Q + r_1 + r_2 + L\rho} \qquad (4)$$

From (3) and (4) we get

$$Q + r_1 + X_2 \rho = P + r_1 + X_1 \rho$$
$$Q - P = \rho (X_1 - X_2),$$

which is an expression independent of the resistance of the end pieces of the bridge, being merely the resistance of that portion of the wire over which we must move in obtaining our two balances. Thompson's device is merely for quickly and conveniently interchanging coils P and Q; with it we must change the position of four copper connectors in four mercury cups; this is tedious and increases the danger of a change of temperature between the adjustments. The modification which I have here has reduced these changes to two which can be made almost instantly. With this device and a carefully calibrated bridge wire it is an extremely simple matter to attain an accuracy of $\frac{1}{100}$ per cent., while much higher percentages of accuracy may be gotten with care. Of course, in this method the coils P and Q must be at a definitely known temperature which shall not change during the taking of the two readings; hence, the two coils are placed in well-stirred water or oil baths. The other coils R and S are wound together and left in the open air as, if they change at all, they will probably change about equally and the result be of no appreciable importance. This device is also the best thing to use in determining temperature coefficients of wires; a length of wire is wound up on a spool, immersed in oil at a definite temperature and compared with a standard. The temperature of the oil is then raised and the resistance of the wire again determined; knowing the difference of temperature and the change of resistance the temperature coefficient follows.

NORTH CAROLINA'S LATEST ELECTRIC RAILWAY.

About the first small town in the United States to attempt an electric railway was Asheville, N. C. Hardly had the successful opening of the Richmond, Va., electric railway been accomplished by the Sprague Company than the work of constructing a road over a route fully as difficult as that in Richmond was begun and when finished demonstrated the ability of the electric system to earn a living in a town of 10,000 inhabitants. The success of this road was widely felt through the Southeastern States, and in North Carolina particularly. There is probably no state in the Union that cannot outrank North Carolina in the point of large towns. Only five reach as high as 15,000 inhabitants, but in four of these, Asheville, Winston, Charlotte and Raleigh, are electric railways in successful operation, and on May 1st, the latest line was opened in Wilmington, the principal town of the State, with a population of 23,000 inhabitants. For four years past there has been in operation the Wilmington Street Railway Company, operating seven small horse cars over about four miles of track; and in December last this line was purchased by a syndicate, several of whom had been instrumental in the organization of the Asheville and Winston roads. In the middle of February the horse cars were withdrawn, and the work of rebuilding the track, building the power station and the overhead lines was begun.

On the principal street the old rail was taken up and a mile of Lewis & Fowler girder rail was laid, while outside of that street the old track was resurfaced and the number of cross-ties doubled. The contract for reconstructing the roadbed and building the overhead lines was let to J. G. White & Co. of 29 Broadway, New York, and was by them completed by April 15. Situated as Wilmington is, in the heart of the yellow pine and juniper country, wooden poles were of course employed, and a neater looking piece of line work cannot be found. The building containing the power plant, car shed and company's offices was designed by Mr. Clarence S. Luce of 181 Broadway, New York, and carried out by Valentino Brown & Co. of Brunswick, Ga., and is a model of convenience and economical construction. The main building is of brick, and the whole of the lower floor 68 x 45 feet is reserved for engines and dynamos. At present a temporary partition is run across one end forming the engineer's storeroom and superintendent's office. The rest of the room leaves ample space for the accommodation of five 15 x 16 foot high speed engines and their dynamos. Should a sixth ever be required, the wooden partition can be taken down and the superintendent's office be moved into the ample space on the second floor. The boiler-room and coal bin immediately adjoining the engine room is also of brick. The former is of sufficient size to accommodate three horizontal return tubular boilers 66 inches x 16 feet; and the latter will hold a cargo of from 450 to 500 tons of coal. Surrounding the engine and boiler rooms is the car shed, with track room for twelve cars, and a freight track for the delivery of coal by rail.

In a Southern climate much attention to ventilation is required, and in this plant excellent results have been obtained. Located on a corner lot on the river front, the engine-room was placed in the corner fronting both streets so that windows could be placed to catch the air on both streets and from the end facing the car shed. The floor was raised five feet above the ground line, and ample air openings were allowed. Through the second story and roof is carried an air shaft 9 x 16 feet to a cupola which creates a strong upward draught. Around this air shaft are located the company's offices, which are particularly bright and airy, and which owe much of their ventilation to it. The steam plant so far installed consists of two 100 h. p. horizontal return tubular boilers 66 x 16 inches; two 15 x 16 inch Ball high speed engines; one Goubert feed-water heater and one Davidson 300 h. p. independent air pump and condenser. The condenser and heater are so connected that they may be used together or separately, or the exhaust may be thrown directly into the air. This plant was installed by the Ball Engine Co. on the general lines laid down in the design of the building, and is a model plant for roads of ordinary size. In the arrangement of the whole much thought has been given to the adaptability of the present installation to future growth.

The supply of water for the condenser is obtained from the Cape Fear River. The boilers are ordinarly fed from the hot well, but for use when the condenser may not be in operation a 3-inch pipe leads to the river and connection is also made with the city mains. From either of these sources of supply the boilers can be fed either through or around the heater by either the feed pump or injector. The station electrical equipment consists of two Edison 100 K. W. railway generators. The car equipment of six open cars and two 16-foot closed cars built by Lewis & Fowler and equipped with two 15 h. p. S. R.S. Thomson-Houston motors. Of the eleven horse cars purchased with the road, four open cars are being overhauled and repainted for use as trailers.

The original mileage of the horse car line has been increased by a mile of new line to a beautiful live oak grove which has been purchased as a park; and, in addition, the company, under its exclusive franchises, has constructed along the wharf front a steam railway, which when completed will connect all the six railways entering Wilmington with all the wharves, warehouses and principal mills of the city. This line is to be operated by a compound steam motor built by the Baldwin Locomotive Works.

Literature.

A Dictionary of Electrical Words, Terms and Phrases. By Edwin J. Houston, A. M. Second edition, rewritten and greatly enlarged. *New York*, 1892. The W. J. Johnston Co., Limited. 562 pp. 7 x 9½ inches. Price $5.00.

The issuance of the first edition of Prof. Houston's dictionary, something over two years since, for the first time placed in the hands of the English reader a work of reference, the need for which was so crying that it is not to be wondered at that the first edition was soon exhausted. With the great demand thus manifested it is a matter for particular congratulation, that the author decided to discard the original plates and to present us with practically a new work. The difference between the old and the new edition can be best realized when it is stated that there are no less than five thousand distinct titles, for which definitions are given, while the cross-references in this edition are copious, and we had almost said in some cases too much so.

At the time that the first edition was published, a large number of newly coined expressions and terms, although they had been used by a few writers, were, it appears, not deemed to have been sufficiently recognized by general usage to warrant the author in inserting them in the work, but we are glad to note that these omissions have now been fully supplied and that the work to-day presents probably as complete an index of the terms of the science and art of electricity as could be well got together.

As regards the definitions themselves they are in the main admirable, considering especially the necessarily limited space which could be devoted to each and still bring the book within reasonable compass; but in glancing over the work we have noticed a few slips to which we would draw attention, not in the spirit of criticism but of friendly suggestion. It might appear to be a useless refinement to have added the pronunciation of the electrical terms, especially those of recent origin, which we notice are pronounced in various ways. Even the word dynamo, one in such common use, is still frequently heard spoken with the accent on the first syllable and again on the second.

The author has frequently, it is true, drawn his definitions from the works of well-known authors, but we think the value of the book could have been increased by quotations in many instances from more than one author, as even in electrical science words have shades of meaning which those who refer to a work of this kind ought to have their attention drawn to. In many instances also a direct quotation would have added largely to the understanding of the definition as given. In some instances we note also the lack of more general information. Thus in defining the term "Electric Current Teaser," the fact that this arrangement, employed by Brush, effected the compounding of the dynamo is not set forth, so that one not versed in the earlier history of the art would fail to obtain a complete comprehension of the term.

While the illustrations in general are good, we note a number of antiquated cuts which represent apparatus that could hardly be called "up to date," and in one instance we notice the employment of an engraving of a ceiling block under the head of branch block. It might be contended that a ceiling block is a branch block in one sense of the term, but the workers in the art would hardly so construe it. We have also noticed in some cases omissions, although not of a serious nature; thus under the head of "Electro-Magnetic Brake" the author has omitted to mention the method of braking by converting a motor into a dynamo, a method now coming into more general use in railway practice, and which is likely to extend in the future. We notice also that the author maintains his original opinion as to the *de jure* inventor of the telephone, as he still accords to Reis the authorship of that instrument. In the case also of the microphone the invention is credited to Prof. Hughes, and the author states that the "forms of transmitting telephones, invented by Reis, Edison, Blake, Berliner and others, are in reality varieties of microphones." We question the advisability, or indeed the right of the author to make categorical statements of this nature in a work of this kind, where there is, or has been, a question involving the authorship of certain electrical devices. We believe, in fact, that it detracts from the value of the work, which should be as far as possible an impartial statement of facts, rather than of opinions. The author has occasionally also thrown in a word, the relevancy of whose position in electrical work is not clear to us, for instance the word "Bioplasm."

Completeness in a work of this kind can hardly be hoped for, and the few suggestions we have made above are offered as an encouragement in the work which Prof. Houston has so successfully undertaken. No one appreciates more than ourselves the tremendous amount of labor involved in the preparation and revision of a work of this kind, and we can only offer our congratulations to Prof. Houston for the admirable manner in which he has succeeded in bringing such a large mass of information within so small a compass.

Letters to the Editor.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted, will oblige by mentioning the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, *203 Broadway, New York city.*

CONCERNING THE "KELVIN."

THE ENGLISH BOARD OF TRADE UNIT is reported to be named the "Kelvin" after the title assumed by Sir William Thomson on entering the peerage. There is a sort of unwritten law that public statues and portraits of people on postage stamps and currency (excepting, as Mr. Thomas D. Lockwood would, no doubt, hasten to remind us, those of Royalty) shall be reserved as posthumous honors. It would be better if new scientific nomenclature were similarly restricted, if only to keep it free from the meddling interference of the British snob.

Lord Kelvin's reputation has been made under the name of Thomson; and as the British Constitution does not contemplate the ennobling of scientific instruments and discoveries, the Thomson galvanometer, the Thomson syphon recorder, the Thomson sounding apparatus, the Thomson compass, the Thomson electrometer, the Thomson effect, and other results of his genius, will continue so universally to be known as such, that it is doubtful if any one (Mr. Lockwood always excepted) will even think of them as the Kelvin galvanometer, the Kelvin recorder, etc., etc. If a unit was to be named after Lord Kelvin, (and the merit of the act is indisputable), what possible objection could there have been to designating it as the "Thomson?" The word is just as short and just as mellifluous as the "Kelvin," and it perpetuates the actual name of the philosopher, and not a mere appendage which is associated with nothing in his career except, perhaps, that amiable failing which has led more than one eminent man to imagine that a title honors him, and not he, the title.

Of course, posterity, in the end, settles these things. It would have preserved the patronymics of Tennyson and Macaulay even if they had not wisely done so themselves. It has refused to sink Pitt in Chatham, Bacon in St. Albans, or even D'Israeli in Beaconsfield. The honors of nomenclature, as witness the "Weber," are sometimes evanescent; and perhaps the "Kelvin" will live no longer than the "Mho" and the "Mac." The "Henry" and the "Franklin" belong to the American Nazareth; and Galvani and Beccaria, and Ritter and Guericke, are likewise to the insular taste open to the objection of being foreigners. But think of Englishmen, in this nineteenth century, passing over Gilbert, and Boyle, and Gray, and Sturgeon, and Davy, and Green, and Siemens, to call a unit after an obscure locality in the "knuckle end of creation," without the slightest claim to notice other than that a peer has chosen its name as the tag to his coronet!

PARK BENJAMIN.

NEW YORK CITY, May 25, 1892.

SHORT'S METHOD OF BRAKING ELECTRIC CARS.

IN THE ELECTRICAL ENGINEER, of May 11, 1892, there appeared an article under the heading of "Short's Method of Stopping Electric Locomotives." I would like to call attention to this as another of the frequent cases in which two inventors strike upon the same idea independently of each other.

The identical arrangement as set forth in the Short article was invented by Mr. Edward H. Johnson, and put in practical operation upon an experimental track in this city in the early part of 1891. The car was fitted with two motors, and a special switch which permitted the brake arrangement to be applied at will.

With this arrangement it was found possible to stop a car in almost its own length whilst running full speed down a very steep incline. As Mr. Johnson's invention was examined by many experts and others who tested the practical working of the method at the time, it leaves, I think, no doubt as to the priority of invention.

Yours very truly,

GEORGE A. SCOTT.

NEW YORK CITY, May 23, 1892.

CONCERT TELEPHONES.

IN your last issue is an article by Herbert Laws Webb, on Long-Distance Telephony. He speaks of a musical performance at New York being heard at Saratoga all over the room by means of a single loud-speaking receiver. Will you kindly inform me how this receiver differs from the ordinary Bell form of receiver and why it is not in more common use?

GEO. A. BAKER.

LEAVENWORTH, KAN.

For these performances a special form of double-pole receiver—much too cumbersome for ordinary use—is employed, a large funnel or resonator being attached to magnify and concentrate the effect. It is well known that musical sounds are always heard much more clearly over the telephone than spoken speech. The ordinary Bell receiver is so sensitive that there is no need of providing a loud-speaking receiver for ordinary service. Besides, a loud-speaking telephone would frequently divulge information to others than those for whom it is intended.—EDS. E. E.

Society and Club Notes.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

AT the May meeting of the council of the Institute, the following gentlemen were admitted to associate membership:

Beals, Pascal P., electrical contractor and agent for the Waddell-Entz Electric Co., 50 Terrace, Buffalo, N. Y.
Berthold, Victor M., with T. D. Lockwood in patent department of American Bell Telephone Co., 16 Upton street, Cambridgeport, Mass.
Bosson, Frederick N., electrician, Calumet and Hecla Mining Co., Calumet, Mich.
Floy, Henry, graduate student in electrical engineering, Cornell University, Barnes Hall, Ithaca, N. Y.
Gross, S. Ross, electrician, Tennessee Coal, Iron & Railroad Co., Ensley, Ala.
Little, Franklin P., manager, F. P. Little & Co., 141 East Seneca street, Buffalo, N. Y.
McRae, Austin Lee, professor of physics, Missouri School of Mines, Rolla, Mo.
Perry, Nelson W., E. M., editor *Electricity*, 6 Park Place, New York City.
Shaw, Edwin C., general superintendent, Thomson-Houston Electric Light and Power Co., 40 Court street, Buffalo, N. Y.
Verley, Horace S. L., with Dr. Wm. E. Geyer, as laboratory assistant, Stevens Institute, Hoboken, N. J.

NEW YORK ELECTRIC CLUB.

THE board of managers of the New York Electric Club, at their monthly meeting, held at the Club House, 17 East Twenty-second street, Thursday, May 19, 1892, elected the following 22 new members: *Active.*—Mortimer M. Hayden, John F. Zebley, E. C. Brown.

Associate.—Geo. Urban, Jr., D. T. Everts, S. L. Phillips, C. I, Hills, J. A. Seymour, A. J. Belden, Chas. J. Mayer, J. Calisch, R. J. Getz, C. H. McIntire, G. F. Wheeler, F. P. Little, John E. McIntosh, Howard H. Crowell, E. T. Pardee, Samuel G. Booker, Chas. R. Lloyd, C. S. Knight, D. F. Urquhart.

A very successful entertainment was given at the club house on Friday evening, May 27, with professional talent. The chief contributions were made by the Brothers Perry, who gave a musical melange with hand bells, musical glasses, sleigh bells, etc.; and the Mendelssohn Glee Club Quartette, composed of Messrs. Prime, Marson, Irving and Hall, who also sang various solos and duets. After the concert, Treasurer Phelps, at the request of President Insull, made an interesting statement as to what had been accomplished in the way of straightening out the club's finances, and then followed a collation served by Mr. Reynolds, the steward of the club.

NATIONAL TRADE PRESS ASSOCIATION.

SOME weeks since a movement was inaugurated in Chicago by the representatives in that city of leading trade and class newspapers, having for its object the perfecting of an association for social intercourse, and for the betterment, in various ways, of the business interests of the advertising solicitors connected with the technical press. Several meetings have been held, and Thursday, May 19, the members met at luncheon and adopted a constitution and by-laws and elected officers for an organization, to be known as the National Trade Press Association.

The representatives of nearly every prominent trade or class newspaper published in Chicago or represented there by a business office have already signed the roll of membership, or have expressed a willingness to do so, and the building up of a strong social organization is confidently predicted. Until permanent quarters are secured, meetings will be held on the first Tuesday of each month at some prominent hotel or club room, when a lunch will be served, papers read, and the regular business of the club transacted. The following is a list of the officers elected for the ensuing year: President, W. A. Carroll, *Scientific American;* vice-presidents, Gilbert C. McDuff, *Johnston's Directory*; J. F. Connor, *Electricity;* Clarence P. Day, *Manufacturers' Record;* D. H. Ogden, *Western Electrician;* treasurer, M. J. Bulkley, *Electrical Review;* secretary, W. Forman Collins, THE ELECTRICAL ENGINEER; directors, J. P. Tuttle, *Western Brewer;* J. W. Dickerson, *Street Railway Journal;* Jno. C. Burnell, *Brewers' Journal.* Such an organization of local representatives of class journals may easily be made very useful as well as agreeable to its members. The title chosen does not seem felicitous as indicating the nature of the association, which can hardly claim to be a national body.

THE NEW ENGLAND ELECTRIC CLUB.

THE NEW ENGLAND ELECTRIC CLUB, which was formed some months ago and which has interested a large number of electrical men throughout New England, formally opened its club house in Boston, last Wednesday. The house is situated at No. 14 Bosworth street and is very centrally located, being within easy reach of all the hotels and theatres. The whole house will be occupied by the club members and it is the intention to keep the first floor for the reception room and the dining room. The front room is given up for reception purposes and as a general room for conversation and reading. The back room on this floor is the dining room and is at present connected with a neighboring restaurant so that members can be served with meals at all times of the day or night. On the second floor is the billiard room, one or two private dining rooms, a kitchen and a wine room. This kitchen will not be used at present but as the club grows larger and stronger it is the intention of the managers to run their own kitchen. The entire third floor is given up to sleeping rooms, of which there are three for the accommodation principally of out of town members who will always be able to find a comfortable room at their disposal at a very moderate price and will feel more at home than by going to hotels. The club house is fitted up with electric lights and last Wednesday evening presented a most attractive appearance. Invitations had been sent to every one interested in electrical business in New England and elsewhere and a very large company assembled to do justice to the entertainment which was provided. In the dining room a récherché cold lunch was provided and a very full and flowing punch bowl occupied a prominent position in the centre of the table. Music was also provided by the Everett Banjo, Mandolin and Guitar Club, who during the evening rendered some very pleasing pieces. Judging from the hearty expressions of the large number who were present on the occasion of the opening night it is safe to predict that the club will be successful, and we hope that with good business management the New England Electric Club will soon take a prominent position in this city of clubs. It is interesting to note that the club house has been furnished largely by the generosity of a number of Boston firms and many of the fixtures have been specially donated. The club started with a membership of two hundred, the majority of whom are paid up members, and if the good will shown by the gentlemen who gathered together on Wednesday evening can be taken as criterion we feel that the interest in the club will grow stronger and stronger and that the membership will soon be increased to three hundred.

The presidency of the club is now filled by Mr. C. S. Knowles, who is well known to the electrical trade as a manufacturer of rubber goods used in the manufacture of electrical apparatus. Mr. Ferdinand K. Wyman who was the first president was obliged to resign on account of his health. The remaining officers are the same as elected at the meeting in Jannary, and are: Vice-President, Mr. E. A. Record, New England manager for the Vacuum Oil Co.; treasurer, Mr. A. O. Smith, treasurer of the Eastern Electrical Supply Co.; secretary, Mr. Lynn M. Hays, night city editor of the *Boston Globe;* directors, Mr. Maybin W. Brown, president of the Eastern Electrical Supply Co.; Mr. Elmer P. Morris, manager of the railroad supply department Thomson-Houston Co.; Mr. Charles C. Pierce, manager of the railroad department of the Edison Co.; Mr. E. R. Tilton, with Pettingell Andrews Co.; Edward W. Sawyer, of Sawyer, Walbridge and Briggs. Great credit is due these gentlemen for the work which they accomplished in getting this club house ready so soon and we can cordially recommend it to every electrical man in New England and elsewhere who desires to have some place where he can meet congenial spirits. The president, Mr. C. S. Knowles is a successful business man of this city and brings with him a large business experience and influence, and has given a large part of the time during the last few months to make the club a success. The other officers and directors of the club are all successful business men of Boston and their names are sufficient to assure that degree of success which the club deserves, and which we hope for and anticipate.

THE INSTITUTE MEETING IN CHICAGO.

ALL the preliminary arrangements for the meeting of the American Institute of Electrical Engineers at Chicago on June 6, 7 and 8 have now been made, and there is every promise of a most successful meeting. Several interesting papers have been added to the programme already published, and over 75 members from all parts of the country have already signified their intention to be present. The Chicago Electric Club has also extended a generous welcome, and will entertain the Institute. The new club quarters will be opened on June 6, and that evening President Sprague will deliver at the club, by invitation, his inaugural address, his subject being: "Coming Developments of the Electric Railway." The New York contingent will leave by special car over the New York Central at midday on Saturday, June 4, arriving in Chicago Sunday afternoon. During the meeting, special trips will be made to the Pullman Works and the World's Fair grounds.

"FROM CHICAGO TO ST. LOUIS BY ELECTRIC EXPRESS."

THE above is the title of a very interesting paper which is to be read at the New York Electric Club on June 2 at 8 p. m. by Dr. Wellington Adams. It will deal with the engineering and commercial problems involved in the proposed high speed electric road between Chicago and St. Louis, and will be illustrated by lantern slides. The subject is of the greatest importance and will no doubt draw a large audience. Dr. Adams has made a specialty of this problem for some time past.

Personal.

MR. SAMUEL INSULL.

THAT the personnel of the executive department of the new General Electric Company is not yet quite settled is made evident by the fact that Mr. Samuel Insull who was but recently elected to the second vice-presidency has already resigned that important position to assume the presidency of the Chicago Edison Company, to which he was elected on Thursday last. It is understood that this will necessitate his removal to Chicago next July, and that he is already taking steps to resign various other offices that from time to time have been loaded upon him. That Mr. Insull should leave New York is a matter of deepest regret to his friends, but they are glad to see his high quality of merit appreciated in Chicago, a city that is always open-hearted to young men of talent. Mr. Insull is still a very young man, yet his record of faithful devotion to Mr. Edison as private secretary, then as the manager of the Edison Schenectady Works, and lately as the executive officer in charge of all the enormous Edison light and power manufacturing is one that he will always be able to take infinite pride in.

The Chicago Edison Company is an organization of wealthy Chicago merchants and bankers, and bids fair soon to be the largest local lighting company in the world. Its capital is $1,000,000 and the first step in increasing it is to $1,500,000, while it is about to build a huge new station whose ultimate capacity, it is said, is likely to be 50,000 or 60,000 h. p. Mr. J. W. Doane is vice-president of the company and Mr. F. S. Gorton, secretary and treasurer.

Prof. George Forbes since his arrival in New York has found his time very fully occupied, the opportunity having been seized by several capitalists and others to consult him with regard to proposed new enterprises. He has recently visited Niagara Falls at the request of the Cataract Construction Co., for whom he is acting in the capacity of consulting engineer in their enormous power transmission project, and has, it is understood, been retained also by the Calumet & Hecla Mining Co. as consulting engineer for their proposed utilization of about 2,000 h. p. in a transmission of several miles in their mines, for the various purposes of ventilation, pumping, drills, haulage, lighting, etc. These and other engagements are expected to detain Prof. Forbes longer in this country than he had at first intended to stop on this trip.

Reports of Companies.

WESTINGHOUSE ELECTRIC AND MANUFACTURING CO.

Owing to an error and some confusion in the figures from which the abstract of the Westinghouse Company's report was prepared for The Electrical Engineer of last week, the reduction of indebtedness was made to appear $100,000 less than it was in fact. Our source of information gave the amount owing on accounts payable January 1, 1891, as $622,469.51, and the amount March 31, as $266,973.19. The official copy of the report just received gives $722,469.51 for January, 1891—showing a reduction in accounts payable of $455,496.32, instead of $355,496.32; making the entire reduction of indebtedness $3,515,334.80.

The name of N. W. Bumsted should be substituted for that of Chas. Fairchild in the new board of directors as printed in our issue of May 25.

The officers elected by the new board are as follows: Chairman, Brayton Ives; president, Geo. Westinghouse, Jr.; first vice-president and general manager, Lemuel Bannister; second vice-president, G. W. Hebard; assistant general manager, W. F. Zimmerman; secretary and attorney, Chas. A. Terry; treasurer, Ph. Ferd. Kobbe; general agent and assistant treasurer, W. C. Clark; auditor, F. H. Ketchum.

NEW ENGLAND NOTES.

The Combination Car Company, of Boston, issued a number of invitations to a large number of street railway superintendents and friends to attend on Saturday, the 14th inst., the inaugural trip of their combination car, which has been put in regular service on the road of the Newton and Waltham Street Railway, and will hereafter make regular trips between these two towns. The party was in charge of Mr. Gilman B. Bolton, treasurer and general manager, and was a marked success in every way. This car, as is well known, can be used either as an open summer car, or a closed winter car, and its many points of superiority were clearly shown on the trip. The passenger sits facing the direction in which he is going, as in a steam car, and the whole car can be instantly changed from a closed car to an open car at will, or *vice versa*. The advantage of this must be apparent to every railroad man, as it entirely eliminates the necessity of having two sets of car bodies, one set of which must be idle during half the year, and the necessity of making expensive changes from time to time as the seasons change. At Waltham, a very recherché luncheon was provided, and a most pleasant day was spent.

The Germania Electric Company, of Boston, whose factory is at Marlborough, Mass., are about to change their offices from the Exchange Building, Boston, to 620 Atlantic avenue, and will hereafter occupy rooms 46 and 47 in that building. Dr. F. A. C. Perrine, formerly of the John A. Roebling's Sons Company, has become identified with this company as its treasurer, and will take charge of the management of the business. Dr. Perrine is well known to the electrical trade all over the country, and will be an important acquisition to the company. The general business of the Germania Company is extremely good, and they have large orders for lamps on hand. With their first-class facilities for manufacture at Marlborough, the Germania Company ought to do a large business, second to none in New England.

H. N. Bates & Co., of Boston, are at present engaged in installing the complete shafting equipment for the new central station of the Haverhill Electric Light Co., at Haverhill, Mass. This contract embraces shafting, pulleys, clutches and all necessary fittings. They have also received the order for the shafting, pulleys, clutches, etc., for the Electric Light and Power Department of the Upper Appomattox Company, Petersburg, Va. They have also got the contract for the whole shafting equipment of the Little Falls Electric Light Company, Little Falls, N. Y. Messrs. Bates & Co. are making a specialty of the question of shafting for electric light and power work, and are particularly well equipped for first-class work. They have also a number of special devices which are peculiarly useful in central stations, and which are all illustrated in the handsome catalogue which they recently compiled.

The Jarvis Engineering Company, of Boston, have just sold to the Consolidated Electric Light Company, of Portland, Me., five 100 h. p. compound condensing Armington & Sims engines of the horizontal type. The Jarvis Company are also now prepared to give estimates and furnish promptly the Wheelock coil heater, for which, we announced recently, they have become agents in New England. These heaters have recently been perfected, and are peculiarly adapted for electric plants, and can now be procured in any size at very short notice.

The Shawmut Fuse Wire Company, of Boston, who make a specialty of manufacturing fuse wire, tested by the Massachusetts Electrical Engineering Company, are in receipt of some very large orders for their product. Experience has shown that a tested fuse wire is absolutely indispensable in modern electric practice, and more and more electric companies are adopting it exclusively. The tag upon which is the name of the Massachusetts Company, is sufficient guarantee of its absolute reliability.

The Page Belting Company, of Concord, N. H., have made the following sales of their Eureka dynamo belt for electrical purposes: Two to Galveston, Texas; one to Chattanooga, Tenn.; two to Roanoke, Va.; one to Seymour, Conn.; one to Boston; nine belts to Brooklyn City R. R. Co., Brooklyn, N. Y.; four to United States Electric Light Co., Washington, D. C.; two to Staten Island Light, Heat and Power Co., Port Richmond, N. Y.; three to the Prudential Insurance Co., Newark, N. J.

The Boston Electric Light Company will commence work, shortly, on the rebuilding of the Stanhope streeet station, which was burned down a few months ago. The building will occupy just the same area as before, but will be more modern in its internal arrangements. The station, when complete, will have a total capacity of about 3,000 h. p. in dynamos and generators.

BALTIMORE NOTES.

The Automatic Switch Co., of No. 8 Keyser Building, has received the following letter from one of the first users of its new Whittingham automatic motor starter. The motor upon which this new service is operating is a 10 K. W. 110-volt Wenstrom, and is used for running a large paint mill, frequently drawing 90 amperes, for 14 hours at a time. The circuit upon which it is operated is subject to many stoppages during the day, and formerly the returning current after each stoppage would blow the fuse before the resistance could be turned in by hand. With the automatic motor starter now in use, the returning current starts the motor without damage, and without the least attention.

> Hershberg Hollander & Co., Importers, Jobbers and Manufacturers of Paints and Painters' and Artists' Materials, 106, 108 and 110 West Pratt Street and 23 West Lexington Street, Baltimore, Md., May 12, 1892.
>
> Automatic Switch Co., No. 8 Keyser Building, Baltimore, Md.
>
> Gentlemen: We take great pleasure in stating that after a trial of six months with your Automatic Motor Starter attached to our 12 h. p. Wenstrom Electric Motor, we are very much pleased. We have found it to be quite valuable, and deem it almost indispensable, and feel quite sure every one using the electric current for power, will find it a valuable acquisition. Having tried other switches, we find that the service we are using at present is decidedly the best, and consider it a perfect piece of mechanism. We wish you great success in the sale of your motor starter, and if we can be of any service to you in showing the working of said motor starter, then you are at liberty to send interested parties to our factory, so that they can fully satisfy thomselves.
>
> Very respectfully,
> (Signed) Hershberg, Hollander & Co.

The Williams Engine Works, 447 North street, are very busy now building engines. Orders are coming in and they are compelled to work at night. They are contracting with another shop to take hold of some of the work. They are building yacht engines, standard steam engines and very high speed engines for direct connection to dynamos. These engines are growing in popularity. With modern tools, advanced ideas and the experience of the past as a guide the builders of this engine are pushing to a leading position. Samuel T. Williams is proprietor of the works.

Mr. P. C. Burns, of Peru, Ind., manager of the Peru Porcelain Works, was a recent New York visitor. Mr. Burns reports excellent business with his company. There is scarcely anything in electric specialties and battery outfits that this company do not manufacture.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED MAY 17, 1892.

Alarms and Signals :—

Time-Call, J. James and J. Jones, Jr., 474,835. Filed July 31, 1891.
An electric annunciator for the use of hotels, etc.

Signaling Apparatus, B. J. Noyes, 474,852. Filed Sept. 17, 1889.
Employs a circuit changer connected with the signal transmitters to cut in, or render inoperative, the audible alarm.

Signaling Apparatus, B. J. Noyes, 474,853. Filed Sept. 17, 1889.
Similar in its object to No. 474,852.

Hotel-Call System, G. P. Greene, 474,907. Filed Oct. 31, 1891.
Provides means whereby each guest may indicate different services required by means of an annunciator in a hotel office.

System of Signaling, H. A. Chase, 474,945. Filed Dec. 18, 1891.
Provides means whereby the signal is indicated by two different characters to denote two different purposes.

Burglar Alarm, R. G. Vassar, 474,980. Filed April 11, 1887.
A burglar alarm operated by the sliding of a bolt.

Electric Signal for Engines, J. C. Rickertson, 475,066. Filed Aug. 31, 1885.
A device for indicating, at any desired distant point, the direction in which a shaft is rotating.

Conductor, Conduits and Insulators :—

Non-Conducting Material, H. W. Jones, 474,834. Filed Jan. 29, 1892.
Consists of a mixture of hair, asbestos and sponge.

Dynamos and Motors :—

Electric Motor Mechanism, E. B. Phillips, 474,857. Filed Dec. 24, 1890.
An axially-placed motor employing a system of internal gears which may be used or thrown out at will.

Armature and Dynamo Electric Machines, S. H. Short, 475,159. Filed Nov. 6, 1890.
Employs a laminated core in combination with end-pieces each consisting of an annulus, and a hub joined by radial arms and having spacing blocks interposed between the end-pieces and the core.

Armature for Electric Motors, E. C. Morgan, 474,818. Filed Dec. 12, 1891.
Comprises a pair of end plates, a cylindrical sleeve clamped between them, and soft-iron cores having coils wrapped about them, the whole enclosed by the end plates and sleeves.

Galvanic and Thermo-Electric Batteries :—

Medical Battery, P. Hathaway, 474,828. Filed April 2, 1891.

Electric Battery. A. S. Keating, 474,912. Filed Sept. 29, 1891.
Consists in placing an annular receptacle around the inside of the battery cell, in which a quantity of oil is placed to prevent the creeping of the salts.

Heating:—

Electrically Heated Matrix-Press, W. Mitchell, 474.964. Filed Dec. 4, 1891.

Electrically Heated Curling Iron, A. H. Watson & F. E. Antonini 475,169. Filed Dec. 1, 1891.

Apparatus for Cooking by Electricity, G. D. Burton & E. E. Angell 475,187. Filed May 28, 1891.
A cooking apparatus in which the heat may be regulated by simply regulating the current.

Electric Cooking Apparatus, G. D. Burton & E. E. Angell, 475,190. Filed May 29, 1891.
A simple electrical device for broiling, roasting, etc.

Lamps and Appurtenances :—

Incandescent Lamp Socket, H. S. Gutman, 474,826. Filed June 29, 1891.
Provides means whereby ready access may be had to the interior of the socket.

Electric Lamp Holder, J. B. Moore, 475,286. Filed Jan. 19, 1891.
An adjustable lamp holder for desks, etc.

Metal-Working :—

Distributing Apparatus for Heating Currents, G. D. Burton, 475,179. Filed May 14, 1891.
Has for its object to distribute heating current of different volumes for forging, etc.

Electrical Forge, G. D. Burton, 475,178. Filed May 6, 1891.
Employs means by which the supporting electrodes may be adjusted readily to receive bars of different lengths.

Electrical Metal Heater, G. D. Burton, 475,181. Filed May 26, 1891.
Method of making twisted metal bars by means of an electric heater.

Method of Electrical Metal-Working, G. D. Burton, 475,182. Filed June 29, 1891.
Relates to the electrical construction of steel and iron tools.

Method of Electrical Metal-Working, G. D. Burton, 475,183. Filed July 1, 1891.
A method of heating particular parts of the bars to be treated without affecting the intermediate parts.

Electrical Converter, G. D. Burton, 475,184. Filed Oct. 21, 1891.
Employs two continuous rings of different polarity on the outside of the converter and connected with the opposite terminals of the secondary coils.

Electric Metal Heater, G. D. Burton & E. E. Angell, 475,185. Filed Feb. 14, 1891.
Employs two series of electrodes in circuit, in combination with a mechanism for automatically reciprocating the metal to be heated between such electrodes.

Metal Heating Apparatus, G. D. Burton & E. E. Angell, 475,188. Filed May 28, 1891.
A forge for quickly heating short pieces of metal.

Electric Heater, G. D. Burton, & E. E. Angell, 475,189. Filed May 29, 1891.
An electric heater for melting metals, etc.

Flexible Electrode, G. D. Burton & E. E. Angell, 475,191. Filed June 26, 1891.
A electrode which will readily yield to the irregularities of the article to be heated in order to enlarge or diminish the contact surface at will.

Electric Metal-Heater, G. D. Burton & E. E. Angell, 475,192. Filed Aug. 3, 1891.
Provides means for the convenient performance of a number of different heating operations from the same converter.

Electric Wire-Twister, G. D. Burton & E. E. Angell, 475,193. Filed Aug. 25, 1891.
A device for heating and twisting wires electrically.

Electric Metal Bending Apparatus, G. D. Burton & E. E. Angell, 475,194. Filed Aug. 24, 1891.

Electric Forge, G. D. Burton & E. E. Angell, 475,186. Filed May 25, 1891.
A forge readily adjustable to receive and easily manipulate bars of different sizes and lengths.

Electrical Forge, G. D. Burton & E. E. Angell 475,195. Filed Aug. 25, 1891.
Provides means for conveniently and economically heating the ends of metal bars.

Automatic Electrical Forge, G. D. Burton & E. E. Angell, 475,196. Filed Sept. 16, 1891.
Adapted to grasp and release automatically the bars to be heated.

Converting System for Electric Metal-Heating, G. D. Burton & A. H. Eddy & G. T. Briggs, 475, 232. Filed Sept. 15, 1891.
Similar to No. 475,184.

Electric Metal Heater, G. D. Burton, 475,264. Filed Aug. 3. 1891.
Provides means for the utilization within a compact space of the induced current from a converter by a number workmen at the same time.

Electric Connectors for Converters, G. D. Burton, 475,180. Filed May 14, 1891.
Secures adjustability of the connectors on the converter whereby the conductors may be readily shifted. Adapted to metal-working.

Miscellaneous :—

Insulated Gear-Wheel, G. F, Lockwood, 474,913. Filed Dec. 10, 1891.

Phonograph, L. S. Clarke, 474,946. Filed Dec. 23. 1889.

Automatic Potential Regulator for Electric Currents, A. L. Ellis, 474,953. Filed Mar. 9, 1891.
Employs a voltmeter in the main circuit, opposed contacts on opposite sides of the needle, circuits connected with each of these contacts each including a motor, and an exciter dynamo, the motors being adapted the one to increase and the other to diminish the strength of field of the exciter dynamo and a resistance being placed in series with the field magnets of the exciter.

Rheostat, A. B. Herrick, 474.957. Filed Oct. 12, 1891.
Employs a resistance conductor wound on each of two insulating frames and a switch the opposite ends of which are movable over such conductors, the latter being uninsulated in the path of the switch.

Terminal and Safety Catch Connection, J. Hutchinson, 474,960. Filed Oct. 12, 1891.
The combination with main and branch terminals of an insulating screen, the positive and the negative terminals being on opposite sides of the screen in order to prevent accidental short-circuiting.

Cupping Glass with Electrical Attachment, F. Thomas. 474,977. Filed Sept. 9, 1891.

Electric Lock, F. Mergenthaler, 475,137. Filed Sept. 10, 1891.
An electric lock for the purpose of holding a door open or closed at will and operated from push buttons located at different points.

Rheostat, W. A. Sterling, 475,255. Filed Nov. 6, 1891.
A rheostat for the purpose of controlling the brilliancy of incandescent lamps.

Railways and Appliances :—

Standard for Electric Wires, E. C. Morgan, 474,847. Filed Oct. 19, 1891.
A trolley wire pole for use in mines, etc.

Electric Locomotive, C. Brown & G. H. Melms, 474,984. Filed Mar. 7, 1890.
Employs a worm-gear driving mechanism.

Electric Railway, J. W. Grantland, 475,107. Filed Jan. 14, 1892.
Employs an overhanging slotted conduit with a hollow conductor through which a blast of warm air or other drying medium constantly passes.

Electric Railway Motor, S. H. Short, 475,160. Filed Dec. 4, 1890.
An axially placed motor for street railways the armature and field magnets of which are both rotatable.

Switches and Cut-Outs :—

Electric Switch, G. Pfannkuche, 474,921. Filed Mar. 1, 1890.
A quick break non-arcing switch for currents of high potential.

Telephones and Apparatus :—

Trunk-Line System, J. J. O'Connell, 474,851. Filed Oct. 4, 1888.
Has for its object to provide ready means of communication directly over the trunk lines between operators at different boards.

ELECTRIC RAILWAY WORK AT PEORIA, ILL.

WORK on the Fort Clark Road is progressing rapidly. Nine cars have arrived. They are from the St. Louis Car Company, and are equipped with McGuire trucks. They are 16 feet long and with open platforms. The boiler-room and engine and dynamo-rooms are completed, and masons are now working on the car house.

The Central Railroad Company are going to tunnel under Central Park and the Rock Island Road to reach Springdale Cemetery which is now only reached by the Fort Clark Road. They have purchased the right of way and the preliminary survey has been completed.

ELECTRIC LIGHTING IN NEW YORK.

IT appears that considerable changes have taken place in the make-up of the United Electric Company, of this city, and that the old Brush Electric Illuminating Company has resumed business on its own account, apparently as a distinct concern. At the annual meeting of the Brush Illuminating Company held this month, Mr. W. L. Pomeroy was elected president, with Mr. G. McFall, secretary and treasurer. Mr. C. W. Spear is general manager, with Mr. A. E. Scoullar as superintendent, and E. W. Stevenson as electrician. It is stated that the Brush Company has ripped out its machines from the United States station in Twenty-ninth street, and taken them back to the Elizabeth street station, where they will now be run.

THE PURITY OIL FILTERS.

THE Purity Oil Filter Manufacturing Company, of 90 Water street, Pitsburgh, report sales of their filters to the Stanley Rule and Level Company, New Britain, Conn., and Carnegie Bros. & Co., Braddock, Pa. They are supplying a long-felt want in large manufacturing plants where the oil got very dirty, so much so that it was not practical to use the ordinary oil filter.

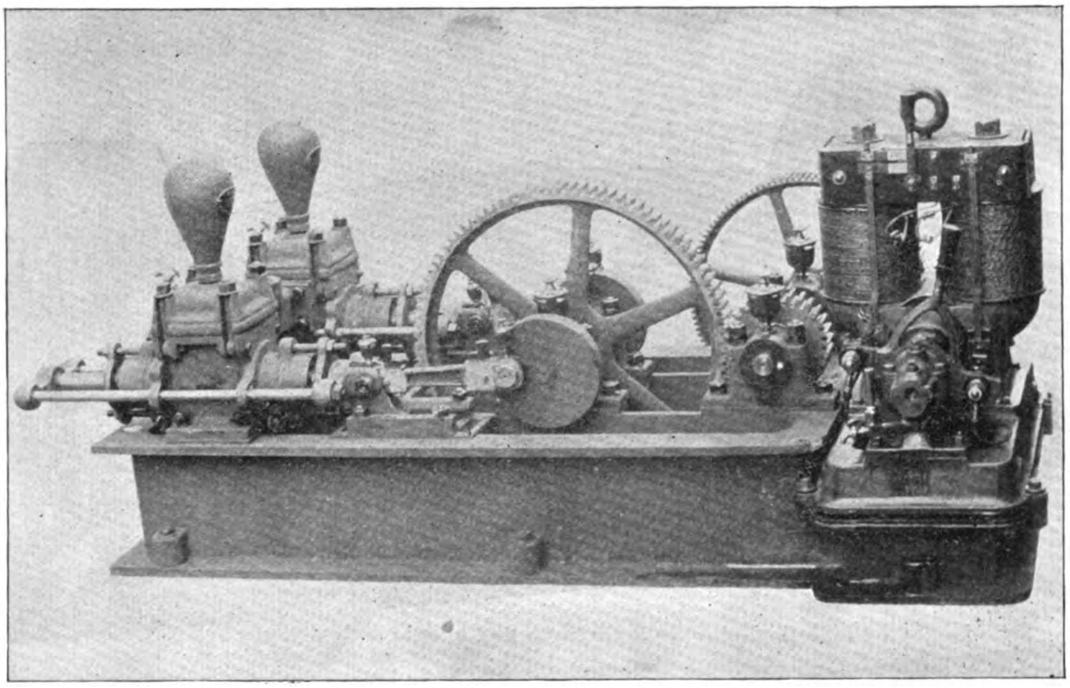
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Printer's ink is the lubricant of business machinery.

A COMBINED EDISON MOTOR AND DEANE DUPLEX PUMP.

A GOOD combination of a pump operated by an electric motor, is the equipment which the Edison General Electric Company are about to put on the market. This consists of an Edison Standard motor of the type of 1885, with a Deane duplex double-acting pressure pump upon one and the same special bedplate. These pumps have outside-packed plungers, with the valves arranged above the cylinder in such a manner that they can be uncovered for examination or repair without removal of any pipes. The covers of the valve chests are held down by swing bolts. To remove these covers it is only necessary to loosen the nuts and swing the bolts away without removing them. The pump is operated by the motor by means of a double gear. The details and arrangement are shown in the accompanying engraving, and are so clear as to require no further description.



COMBINED EDISON MOTOR AND DEANE DUPLEX PUMP.

TEST OF THE PATTON MOTOR.

A PRACTICAL test of special interest to street railway men took place at Pullman, Ill., on May 10. The occasion was the trial trip of the improved Patton engine-motor, built on order for service at Portland, Ore. While the details of this motor have already been made public, a general review of its essential features will be read with interest by all those who look for improvement in street car propulsion.

This is the first attempt to combine an electric generating plant with a driving motor, placed on a moving vehicle for traction purposes. The combination embraces a gasoline engine which drives continuously a dynamo for generating electricity, and a set of accumulators to insure a constant supply of electricity sufficient to meet the various requirements of street car traffic.

The gasoline for the engine is stored in tanks at the top of the car. The engine being entirely automatic, and being connected to the dynamo by a friction pulley, it operates as long as there is gasoline in the tank. When descending a grade, carrying a light load or standing still, the surplus current of electricity is thrown into the accumulators, to be used only when an excess of the normal power is needed. Thus the storage cells are always ready to receive that part of the current which would otherwise be lost, and to return it to the motor at such times as it is required. One of the principal features of the apparatus is that it is entirely automatic.

The inventor has arranged his cells so that they are never fully discharged, thereby removing what has hitherto been one of the greatest drawbacks to the storage battery for this work.

A unique feature of the motor is that in preparing for the daily run, the accumulators can send their energy into the dynamo, which then becomes a motor, thereby starting the engine and running it until the gas power reaches proper control; then the current is reversed, and the normal operation of the engine and dynamo commences. The labor thus required to run the car is limited to the ordinary motorman who handles the controlling switch and brake at either end of the car.

The motor may be constructed as an independent car to draw trailers, or it may be designed as a combination car, carrying passengers at either end.

All the foregoing valuable features of the motor were fully calculated out by the inventor, and have been more than realized in actual operation. The car has been running on the tracks at Pullman several weeks, and was subjected to the severest tests in climbing grades of 10 per cent., and in rounding curves at its normal speed of twelve miles an hour. We are indebted for the above details to Mr. M. J. Sullivan, the editor of the *Street Railway Gazette*, of Chicago. The motor used on the car proper is of 20 h. p., and the entire engine weighs about 14,000 pounds.

W. R. FLEMING & Co., Mail and Express Building, corner Fulton street and Broadway, this city, are installing two "Ideal" self-oiling high-speed engines in the new Naval Observatory at Georgetown Heights, Washington, D. C. As is well known, there is no more exacting customer than the Government, and these engines were selected by Lieut. A. V. Zane, of the Naval Department at Washington. After bids were received, he visited this city to investigate the merits of the different engines, and personally visited the engine-rooms to see them run. He also visited other cities for the same purpose, and on his return to Washington, the "Ideal" engines were ordered. His reason for ordering these engines was, as he expressed it, their perfectly noiseless running, as the offices in the Observatory, in order to use their instruments with accuracy, can have no noise or vibration of any kind (which would affect their proper use) in the building, and on investigation, Mr. Zane thought these engines exactly suited to his purpose.

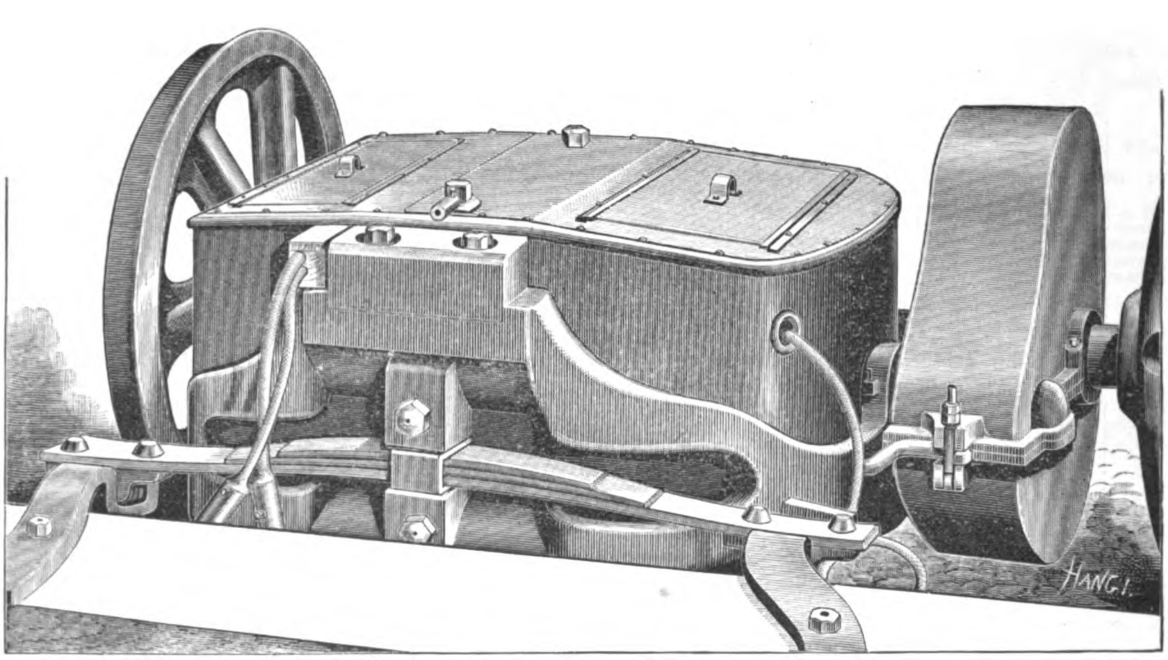
COMMONWEALTH IRON CO., Commonwealth, Wis., have recently purchased a 35 h. p. Ball engine from the Ball Engine Co., Erie, Pa.

IMPROVED WIGHTMAN 25 H. P. RAILWAY MOTOR.

The Wightman Electric Manufacturing Co., of Scranton, Pa., has again made several improvements in its street railway motor, the latest type of which is illustrated in the accompanying engraving. These improvements relate chiefly to the protection of the field windings and working parts of the motor against damage from external agencies. It will be seen from the illustration that the motor is entirely encased in a metal armor. This casing is made of sheet steel firmly riveted to the motor frame and in such a manner as to make the motor practically dust and water-proof; the arrangement of the armor also permits of ample ventilation. The under side of the motor, which does not show in the illustration, is protected in the same manner as the upper portion. This sheet steel casing does not add materially to the weight of the motor, but at the same time it offers just as much protection as the heavy castings employed in many instances.

The gear case used with the Wightman motor has also been greatly improved. It is now made of malleable iron and is in three parts, very easy to attach or take off. The arrangement of this gear case is such that no bearing parts are necessary, thus eliminating all wear on the case. It is absolutely dust-proof, and the parts are so fastened together that they will not work loose.

The controlling switch used is of the standard Wightman type, having speed controlling handle and reversing handle combined in one, making the operation of the simplest possible character. Speed regulation with this controller is obtained without the use of any external resistance above a car speed of three or four miles an hour. There are five speed contacts possible for either direction of operation.



Improved Wightman 25 H. P. Railway Motor.

Some tests recently made by Mr. J. T. Gardiner, consulting electrical and mechanical engineer at St. Joseph, Mo., where the Wightman system entered into competition with other well-known systems, gave flattering results for the Wightman apparatus. The Wightman system is now in successful operation on a great number of roads among them the following: The People's Street Railway, Scranton, Pa.; The People's Street Railway, St. Joseph, Mo.; Pennsylvania Motor Company's road at Easton, Pa.; Auburn City Railway, Auburn, N. Y.; City Passenger Railway, Altoona, Pa.; Wheeling Railway, Wheeling, W. Va.; DuBois Traction Passenger Railway, DuBois, Pa.; Brooklyn Street Railroad, Cleveland, Ohio; East Cleveland Railroad, Cleveland, Ohio.

EDISON MOTOR IN A NEWSPAPER OFFICE.

The proprietors of the *Daily Palladium*, New Haven, Conn., have, among other improvements made in their plant, discarded their steam engine, and adopted electricity as the motive power for their presses. The Edison General Electric Company have installed one of their 12 h. p. motors in the Palladium Building and the paper observes: "The motor occupies very small space, is noiseless, easy to manage, and does its work quite as effectively as the cumbersome and more expensive steam engine, and at far less expense."

SAFETY INSULATED WIRE COMPANY.

One of the best evidences of the rapidly growing popularity of the productions of the Safety Insulated Wire Company is demonstrated by their recently acquiring a most desirable addition to the quarters which they already occupy. Mr. L. F. Requa, treasurer and manager of the company is authority for the information that his company have secured the large six-story building in the rear of their present factory. The new building has a frontage of 100 feet on Twenty-eighth street and is 150 feet deep. The securing of these premises is most fortunate as it is directly in the rear of their present factory and with very slight changes can be desirably connected with all the existing departments. When completed the combined buildings will represent considerably more than double the space at present occupied by this company. The Safety are rapidly pushing to the front as one of the largest and most popular manufacturers of insulated wires.

ELECTRICAL GROWTH AT SEATTLE, WASH.

D. T. **Denny**, president of the Rainier Power & Railway Company, has made a contract which covers the construction and equipment of the new Third street railway and an extensive electric lighting system. The power station is at the Western Mills, on Lake Union. The "Short" system of railway motors has been selected and the St. Louis Car Company will build the cars, of which there will be six of the handsome vestibule type. The present lighting plant will be increased by 2,000 incandescents and 100 arcs. The National alternating, or long distance, system will supply the former and the Western Electric arc system has been adopted for the latter. This will be the first appearance of these electric systems in this State, except at Spokane, where the "Short" is used.

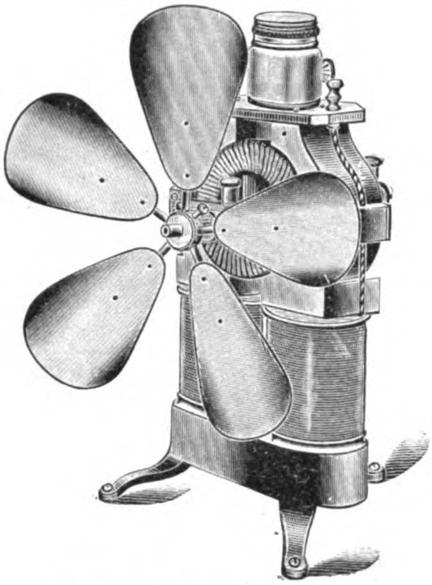
A 300 h. p. "Ideal" steam plant will also be put in at the power station, as well as two 80 h. p. National railway generators. This contract, including five miles of street construction, was awarded to the local contracting firm of Charles H. Baker & Co., who have placed their order for the steam plant with Power & Collins, also of this city.

About $100,000 will be expended under this initial contract. It is expected that cars will be running on Third street about August 1, and construction will begin without delay.

Detroit, Mich.—Frank B. Rae has brought suits against the Detroit Electrical Works for $20,000 and $25,000, respectively. His ground for one of these suits is that the defendant corporation has paid him no royalties since he severed his connection with it last fall. He asserts in the other, that the affairs of the Works were manipulated so that he was frozen out of some bonds issued by the corporation. For instance, he says that the electrical company bought up the stock of the National Traction Company which proved a loss and that this loss was assessed to the bondholders like himself.

THE LITTLE DIAMOND FAN MOTOR.

The Little Diamond fan motor shown in the accompanying engraving is manufactured by Clark & Marshall, No. 413 "The Rookery," Chicago. They have spared no expense or pains to make it perfect, complete and attractive. Among its many good features may be mentioned the ring armature which is valuable for ventilation, and in thus keeping the armature cool its electrical resistance is reduced and danger of burning is avoided. It stands 14 inches in height and has a 12-inch bright brass fan. The bearings are wide and are self-oiling.



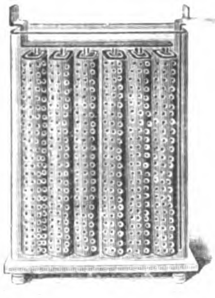
Little Diamond Fan Motor.

The Little Diamond may be regulated for two speeds, namely, 800 and 2,000 revolutions per minute. There is no sparking on the commutator, the brushes being regulated by a spring brush-holder which keeps the brushes in their proper position. This motor is designed for a direct incandescent current and may be put in operation by merely attaching it to a socket by plug and cord. It runs noiselessly and is neat in appearance.

Messrs. Clark & Marshall have increased their facilities for the manufacture of their "Little Diamond" and will be able to supply the great demand for them during the season.

THE FORD-WASHBURN STORAGE BATTERY.

The accompanying illustration shows the latest form of storage battery cell manufactured by the Ford-Washburn Storelectro Company, of Cleveland, Ohio, and already used in railway work. As will be seen, six sets of elements are employed, the negative completely surrounding the positive and consisting of receptacles of especially prepared lead perforated to allow the acid to percolate readily. The holes are not sufficiently large, however, to permit any active material to force its way out. The positive element consists of a porous pot containing active material surrounding a conducting medium of perforated lead so arranged as to compensate for expansion and contraction. The negative elements touch one another and are connected by a solid lead strip welded to all of them at the bottom, while the positive elements are similarly connected at the top. By this arrangement an evenly distributed discharge of extra strength is given to the battery. As the positive and negative elements are only separated by the porous partition one-eighth of an inch thick the internal resistance is inappreciable, while a short-circuit is impossible. The cases are made of hard rubber, tightly sealed, and the battery, after being placed upon the car, requires no attention except an occasional replenishing of the acid.



Ford-Washburn Storage Battery.

It is claimed that short-circuiting these cells and completely discharging them at the highest possible rate does them good instead of injuring them. This is an experiment constantly made. The following table gives the results of a test of six hours at the end of which time the battery was by no means completely discharged, and would, if left to itself, have risen to almost normal.

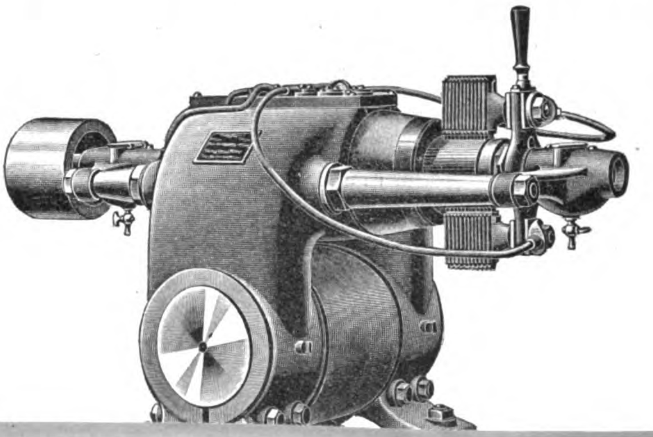
Readings from one cell.

THE NEW JENNEY MOTOR.

The motor illustrated herewith is of the well-known Jenney type, but several new features have recently been added. All field coils are now wound upon insulated spools and afterwards slipped over the cores. The bearings are self-oiling, and in the larger sizes self-aligning. Brush holders fitted with composite carbon brushes are so attached to the rocker-arm that the carbons always press upon the commutator at diametrically opposite points. Machines above one horse power are fitted with sliding base and belt tightener. These motors are made either shunt or series in all the standard sizes and voltages. The Jenney Company, of Indianapolis, Ind , also manufacture a complete line of dynamos and power generators.



The Indiana Rubber and Insulated Wire Company, have moved their head offices from Jonesboro, Ind., to 242 Madison street, Chicago, where business will be handled hereafter. Mr. C. J. Butler is the manager of this office and with his energetic and pushing qualities will no doubt largely increase the business done by the company, who manufacture a very high grade of goods. The factory, to which have been added increased facilities, still remains at Jonesboro.

DAY'S KERITE WIRES AND CABLES.

The following circular has just been issued from Kerite headquarters, in the Mail and Express Building, 166 Fulton street:

> New York, May 18, 1892.
>
> *Gentlemen*—Having undertaken the general mangement of the long-established business of S. A. Day (successor to A. G. Day), manufacturer of the celebrated Kerite insulated wires and cables, I am prepared, after an experience of thirteen years in superintending and improving their manufacture, to supply materials of the highest standard attainable.
>
> My personal close study and contact with the practical part of this business will enable me to meet the wants of customers in every detail, and I bespeak a continuance of favors so generously accorded in the past.
>
> Very truly yours,
>
> W. R. Brixey,
> General Manager.

NEW YORK NOTES.

The Ball Engine Co., of Erie, Pa., represented in New York by Mr. F. R. Chinnock, report the following sales and shipments of recent date: Maryland Steel Co., Sparrows Point, Md., one 50 h. p. simple engine; Wilmington Street Railway Co., Wilmington, N. C., two 130 h. p. simple engines and complete steam plant; J. C. Hubinger Co., Keokuk, Iowa., one 300 h. p. cross-compound engine and condenser; J. W. Parker & Co., Philadelphia, Pa., one 50 h. p. simple engine; Chesapeake Light & Power Co., Hampton, Va., two 150 h. p. tandem compound engines and transmitting machinery; Moundsville Electrical Co., Moundsville, W. Va., one 130 h. p. simple engine; Niagara Falls Street Railway Co., Niagara Falls, N. Y., two 130 h. p. simple engines and steam plant complete; Electric Light Co., Elizabeth, N. C., one 100 h. p. simple engine; Philadelphia House of Refuge, Philadelphia, Pa., two 50 h. p. simple engines, one 100 h. p. simple engine; Edison General Electric Co., State House, Trenton, N. J., one 35 h. p. simple engine; Schuylkill Electric Railway Co., Pottsville, Pa., one 250 h. p. simple engine; Electric Light Co., Doylestown, Pa., one 130 h. p. simple engine; Somerville Hotel, St. Clair, Mich., one 35 h. p. simple engine and steam plant; Freeport Gas & Electric Light Co., Freeport, Ill., one 130 h. p. simple engine; Warrenton Electric Light Co., Warrenton, Mo., one 50 h. p. simple engine; Pittsburgh Iron & Steel Engr. Co., New Castle, Pa., one 50 h. p. simple engine, one 80 h. p. simple engine.

The Sprague Elevator has received its baptism of fire. About 6 o'clock A. M. on Thursday last a fire broke out on the third floor of the Cassidy Building, which burned through to the fourth floor, where the elevator is, and made general havoc before it was subdued. On the first inspection the elevator looked as if it were badly disabled. Insulation had melted from wires, switches had burned off, fuses gone, the controlling cylinder was split, the regulating gear was stiff and somewhat distorted, and the whole machine blackened and clogged with mortar. Part of the machinery had been flooded. It was 12 o'clock before anything could be done towards removing debris, but at 7 o'clock at night the elevator was in operation. It seemed altogether a remarkable test of reliability of electrical apparatus when well constructed. Photographs of the place were taken and are curiosities as pictures of apparent utter wreck.

The Ball & Wood Company, of 15 Cortlandt street, New York, has just shipped the eighth 150 h. p. engine within as many months to the Edison Electric Illuminating Company, of Paterson, N. J. In addition to this average of one engine per month, they have also furnished to the same company one of their improved 300 h. p. compounds. Visitors to the Ball & Wood shops at Elizabeth will now see over thirty engines under construction embracing types of their improved simple, tandem compound and cross-compound engines all on contract and in preparation for early delivery.

WESTERN NOTES.

Mr. William H. McKinlock, president of the Central Electric Company, has returned from a successful extended Western trip, having called upon many of his old friends, and customers of his company, and making many new ones. Mr. McKinlock secured an order for the entire underground electrical system of one of the larger Western cities, where Okonite wire to be used, besides other valuable trade.

Mr. M. J. Sullivan has purchased the *Street Railway Gazette* which will hereafter be conducted under his management. His brother, Mr. M. C. Sullivan, formerly connected with The Electrical Engineer, will represent him in the East. Mr. E. F. Seixas, for many years in the Edison service, will be his business manager, and Bishop & Fiske, 11 India street, Boston, will be his New England representatives. The New York office will be at 136 Electrical Exchange, and the Chicago headquarters will be in the Phenix Building. Young Mr. Sullivan has won a great many friends by his energy and ability, and bids fair to make a great success of his paper as a weekly in this field. It is understood that the first issue under his individual control will come out this week.

The Electric Appliance Company have found a new use for flexible conduit, and in addition to filling large orders for interior work, are selling a large amount as a substitute for hard-rubber tube. It is adapted for this purpose on account of its flexibility as it can be bent in any shape without injury. It also has another advantage over rubber, being non-combustible and unaffected by atmospheric action, oils or acids. As it comes in long lengths it can be cut and used in any lengths desired, thus avoiding the waste unavoidable with hard-rubber tube or any substitute for it which comes in short lengths.

Mr. William P. Williams, the well-known electrical engineer of Cincinnati, and Mr. James H. Harrison, secretary and treasurer of the Police Telephone & Signal Co., of Chicago, were callers at the Western office of The Electrical Engineer last week.

Messrs. Sargent & Lundy, the well-known consulting and contracting electrical engineers, have removed from their office in the Rookery to suite 1421 Monadnock Building where they have very handsome and commodious offices.

Mr. T. Ahearn, a member of the firm of Ahearn & Soper and also manager of the Ottawa Electric Railway Company, was a Chicago visitor last week and received his customary warm welcome from his many friends here.

Mr. H. E. Seemuller, general advertising representative of the Yale & Towne Manufacturing Co., Stamford, Conn., is spending a few days in Chicago and was a caller at the Western office of The Electrical Engineer.

Mr. James McKearney, well known in electrical circles in St. Louis, dropped in at the Western office of The Electrical Engineer last week. He is spending a few days in the city combining business with pleasure.

The Central Electric Company report considerable activity in the sale of Okonite wire, their orders for the current week aggregating one-half million feet, Manson and Okonite tape being in fair demand, as well.

Mr. Geo. A. Davis, secretary and manager of the Neenah and Menasha Gas and Electric Company, Neenah, Wis., spent a few days in Chicago last week.

WASHINGTON NOTES.

The Washington & Arlington Railway Co., whose road is being equipped with the Wheless underground electric system, have 2 of their 4½ miles completed. The conduits are being laid and the underground work will be in readiness in about three weeks. The engines and dynamos are in position and it is expected the first car will be put in operation by the first of June. On that part of the line now being completed the travel at time reaches 30,000 passengers per day, which will give the Wheless system the severest test. This portion of the road will have an equipment of eight cars. The company will start on the construction of a $200,000 bridge across the Potomac River this summer, and it will be adapted to the use of the underground system. It was only after the long and successful operation of one-half mile of experimental road which was constructed at a cost of over $50,000 that the Washington & Arlington Co. consented to adopt the Wheless system.

Congdon, Bliss & Daniels are installing a 300-light plant of the Edison system in the Oregon Avenue Apartment House; a complete 150-light Edison plant on the steamer "River Queen," now under construction at Baltimore, and have just completed the wiring of the Washington Light Infantry Armory for 300 lights. This enterprising firm are selling fan motors by the ton.

The Hanson Battery, Light & Power Co. will bring out something during June which will be very interesting to all yachtsmen.

THE
Electrical Engineer.

VOL. XIII. JUNE 8, 1892. No. 214.

ELECTRICITY AT THE BELMONT AND SHERIDAN MINES, TELLURIDE, COLORADO.

BY

J. H. E. Waters.

IT HAS seemed to the writer that a short description of the electrical plants in use at the Sheridan and Belmont mines may prove of interest as an example of the solution of the problem of utilizing water-power situated at a distance from the points of operation; especially as in one of these instances, the cost of packing coal to the mines practically prohibits the use of steam. The mines named are in the vicinity of Telluride, a large mining centre, of which a very characteristic street view is here given in Fig. 2; while the contour of the country and the position of the electric plants may be fairly judged from the outline sketch presented in Fig. 1.

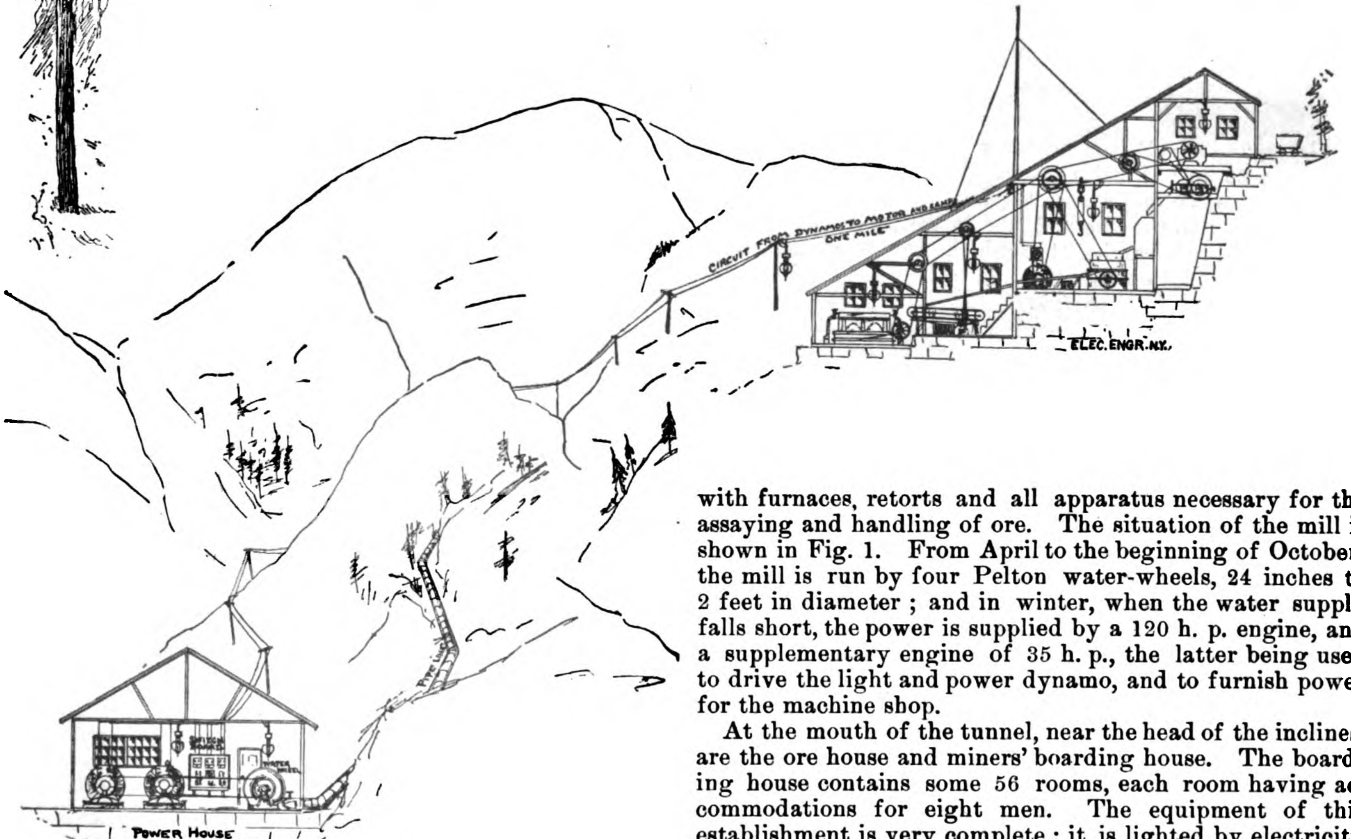

FIG. 1.—AN ELECTRIC TRANSMISSION AT TELLURIDE, COL.

The mines of the Sheridan Consolidated Mining and Milling Company are amongst the most productive in Colorado, and under the management of Mr. J. H. Ernest Waters have reached their present condition of successful and economical development. The mouth of the main crosscut tunnel is at an elevation of 2,700 feet above the terminus of the Rio Grande Southern Railroad, and at a distance of about 1¼ miles. The ore is brought down on a double track inclined cable road, 24-inch gauge, laid out and built under the direction of Mr. Waters. An endless cable is employed, and the cars are attached to the cable by a "chain clip" (patented by Mr. Thomas J. Waters, formerly of the Westport Coal Mining Company, of New Zealand), which has proved eminently satisfactory on grades up to 35 per cent., as on these inclines, and when every other device for this purpose has proved unsuccessful. The Sheridan concentrating mill is situated at the foot of these inclines, and has a capacity of 100 tons per day. It comprises crushers, stamps, Frue vanners, etc., and is provided with furnaces, retorts and all apparatus necessary for the assaying and handling of ore. The situation of the mill is shown in Fig. 1. From April to the beginning of October, the mill is run by four Pelton water-wheels, 24 inches to 2 feet in diameter; and in winter, when the water supply falls short, the power is supplied by a 120 h. p. engine, and a supplementary engine of 35 h. p., the latter being used to drive the light and power dynamo, and to furnish power for the machine shop.

At the mouth of the tunnel, near the head of the inclines, are the ore house and miners' boarding house. The boarding house contains some 56 rooms, each room having accommodations for eight men. The equipment of this establishment is very complete; it is lighted by electricity and heated by steam. The ore house is at the mouth of the tunnel, where the ore coming from the mine is sorted, the high-grade, or smelting ore being sacked and shipped directly to the smelters, while the second-class, or concentrating ore, goes to the mill.

The electrical work consists in lighting the inclines, which are snow-shedded for the greater part of their length, the ore house, boarding house, tunnel, and the main Sheridan shaft, and in furnishing power for the crushers in the ore house, and for hoisting in the mine. A "C. & C." dynamo, of 30 k. w. capacity is placed in the mill at the foot of the inclines, and while water is available, it is

FIG. 2.—A CHARACTERISTIC STREET SCENE IN TELLURIDE, COL.

driven by a 28-inch Pelton water-wheel; and during the winter, by a 35 h. p. Ideal engine. The circuit from this dynamo follows the inclines up the mountain a distance of about 8,000 feet to the ore and the boarding houses, and from this point, it is carried through the tunnel a distance of 3,300 feet, and then up the Sheridan shaft, a further distance of 1,000 feet, to the upper levels of the mine. There are 250 to 300 lights on this circuit; and in addition to these, there is a 10 h. p. motor in the ore house, which furnishes power for the crushers, and a 5 h. p. electric hoist in one of the shafts. The dynamo operating these circuits has been in constant use day and night since starting, without the least hindrance or delay of any kind, and works equally well under all conditions and changes of load. The relations of the dynamo windings to the resistance of the main circuit are in fact so nicely proportioned that the throwing on and off of the ore crushers or hoist has scarcely any perceptible effect on the lights which surround them at a distance of 8,000 feet from the dynamo.

The plant installed for the Belmont Consolidated Mining Company is of much greater capacity, and is used exclusively for operating the mill, which is located near the top of the range, in what is known as the Savage Fork of Marshall Basin. In elevation it is about 3,000 feet above the power house, and the length of the line or circuit between the two is something over 11,000 feet. The distance, however, by the trail, is about four miles. In constructing this line, great care was used to avoid places where snow slides score the mountain sides every winter. At one point, the line is carried across the path of a very heavy snow slide a distance of 800 feet, each leg of the circuit being suspended from a three quarter-inch steel cable, which is securely anchored at each end. The situation of the power house is shown in Fig. 4. The water supply is taken from the head of the stream supplying the Sheridan mill, and the location of the power house being above the level of the Sheridan flume, the tail water is carried across the gulch, as shown in the cut, and made to do duty for the concentrating mill below. In this power house are placed two 30 k. w. C. & C. dynamos, as shown in Fig. 5. This also shows the 36-inch Pelton wheel (under a head of 670 feet, and able to develop up to 210 h. p.) coupled direct to the end of the driving shaft. In the mill are placed two 30 h. p. motors, two motors being used instead of one for convenience in packing up the trail. The machinery in the mill consists of two Dodge crushers, one set of large duplex Cornish crushing rolls, three 5-foot Huntington mills, three Frue

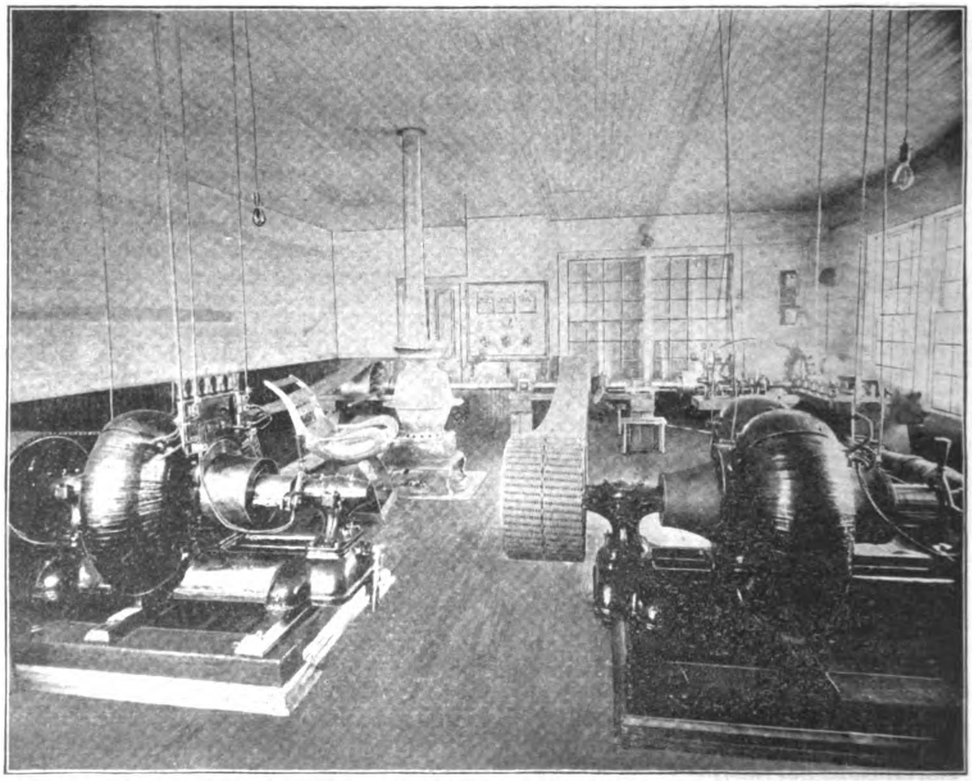

FIG. 5.—C. & C. POWER PLANT, BELMONT MINE, TELLURIDE, COL.

vanners, and six bumping tables. This machinery was furnished by Messrs. Fraser & Chalmers of Chicago.

The operation of the Belmont plant, so far, has been of the most gratifying character. During the initial run last year, and since starting up again this season, the behavior of the electric machinery has been uniformly satisfactory. The "drop" between the generators and the motors, a distance of about two miles, is only about 8 per cent.

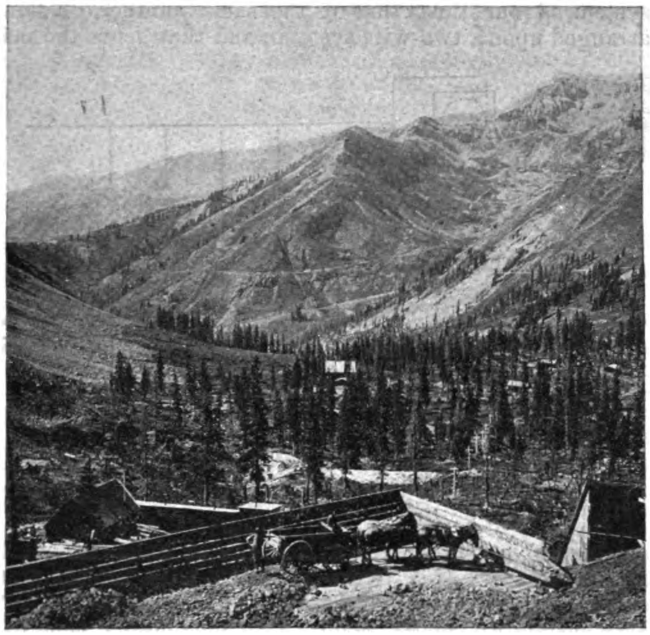

FIG. 3.—SHERIDAN MINE PLANT, SHOWING POLE LINE THROUGH TREES.

This machinery was manufactured by the C. & C. Electric Motor Company, and installed under their supervision; and it may safely be said, in view of the excellent results obtained, that it constitutes one of the most efficient and successful electrical mining plants in this State. A faint idea of some of the difficulties encountered in installing the plant may be gathered from Fig 6, which shows the slow and laborious hauling of the boilers up a steep mountain side.

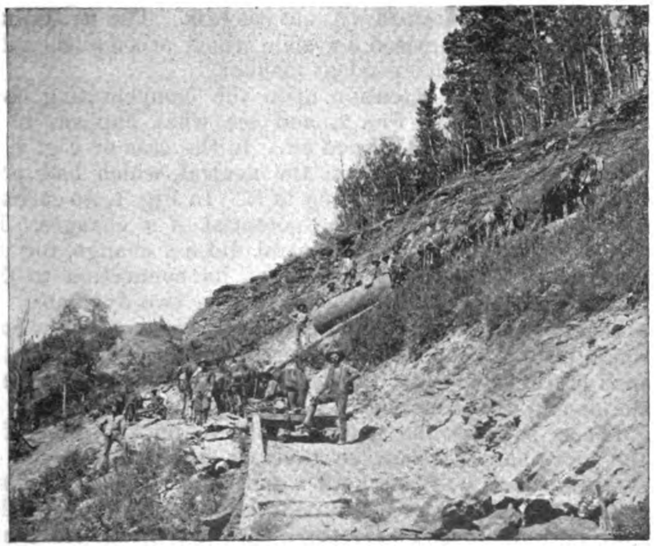

FIG. 6.—HAULING BOILERS UP THE MOUNTAIN.

A BISMUTH BATTERY.

If two bismuth electrodes are plunged into a vessel containing a solution of bismuth-chloride, or of hydrochloric acid, and if one of the electrodes is placed between the poles of an excited electromagnet, a galvanometer will show that a current flows in the liquid from the magnetic electrode. This current is always in the same direction. The electromotive force varies with the electrodes and the solutions; in certain cases it may attain .0023 Daniell when the magnetic field $= 815000\ H$, where H is the horizontal component of the earth's field. This current, says G. P. Grimaldi in *Il Nuovo Cimento*, Vol. XXV, p. 191, is due partly to the motion of the diamagnetic liquid, which is caused by the magnetic field, and it also seems to depend on the peculiar effect which magnetism appears to have on the position of bismuth in the electro-contact series.

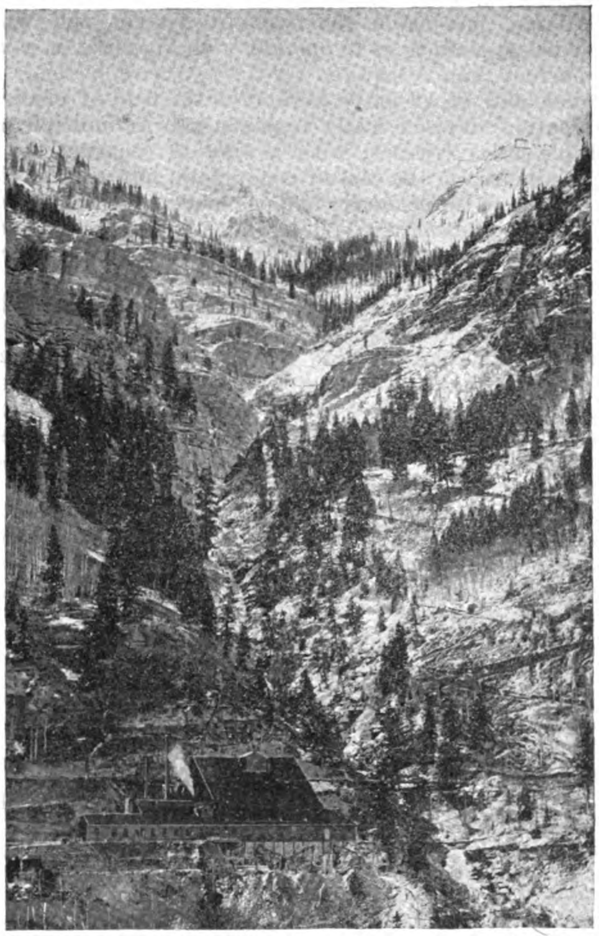

FIG. 4.—ELECTRIC POWER HOUSE FOR THE BELMONT MINE.

THE ROYAL SOCIETY.

JOHN AMBROSE FLEMING, D. Sc., who holds with distinction the chair of electrical engineering in University College, London, is one of the candidates selected by the Council of the Royal Society for election into that body. Dr. Fleming is the author of "The Alternate Current Transformer in Theory and Practice," and of many papers published in the proceedings of the Royal Society, the Institute of Electrical Engineers, and the Physical Society. Dr. Fleming gave a course of lectures at the Royal Institution on the induction coil and transformers, as well as a discourse on the experiments of Professor Elihu Thomson on the phenomena of electromagnetic repulsion.

A NEW THREE-WIRE SYSTEM.

BY

H Ward Leonard

IF there were no limit to the voltage of economical incandescent lamps we should have no especial use for the three-wire system. But, since the voltage of commercial incandescent lamps is comparatively low, the conductors required for a direct continuous current distribution on the two-wire system makes the cost of copper excessive, even at the shortest distances met with in central station practice. Therefore, there is a very great advantage in a system which enables us to operate with independent control of each lamp, just as in the two-wire system, and which nevertheless enables us to operate with higher E. M. F. and less current than is required for the two-wire system.

Brush and other early workers in the field of electrical distribution devised many ingenious series-multiple and multiple-series systems, with a view of securing the desired reduction in the cost of conductors; but none of these systems gave the necessary independence of each lamp, without auxiliary automatic devices, which were not sufficiently simple and reliable for a general commercial supply of electricity.

One of the earliest systems of this kind was devised by Edison, and is probably still in operation at Roselle, N. J. In this system one dynamo was used, having an E. M. F. three times that of the lamps, and at every point where light was required three lamps were installed in a group. The failure of any one of these three lamps extinguishes all three and they must be all of the same candle power, which does not give a sufficiently flexible system.

Fig. 1 shows a two-wire system having a dynamo whose E. M. F. is double that of the lamps which are arranged two in series, with a conductor which joins the point between each pair of lamps to each similar point between every other pair of lamps.

It will be evident that, in this system, if any one lamp, say, in group A, be extinguished, no other lamps will be extinguished thereby; but since the dynamo produces a constant E. M. F. and since now the resistance of group A is increased and is higher than the resistance of group B, the fall of potential will not be the same as before, the fall of potential on group A being greater than that on group B. That is, while the potential of the compensating conductor N was exactly midway between that of the two outside conductors P and M when the number of lamps in groups A and B were equal, the potential of N is now not midway between that of the main conductors, but is nearer that of M, so that the E. M. F. on lamps A is greater than the E. M. F. on lamps B.

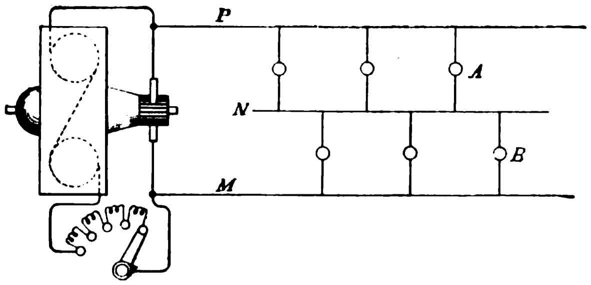

FIG. 1.

Edison devised his three-wire system to overcome this difficulty, and made use of a source of energy divided into two sources of equal and constant E. M. F. in series with each other and each having an E. M. F. equal to the E. M. F. of the lamps.

Edison's three-wire system in its usual form is shown in Fig. 2, and it is so familiar to all that I need only state that the resistance of the lamps, as grouped in a three-wire system, is four times that of the same number of lamps arranged upon a two-wire system; and that hence the main conductors of a three-wire system can be made one-quarter the size of those of a two-wire system with the same percentage of loss in the conductors. That is, while in a two-wire system we would require two conductors, each of a size and weight which we may call 1, the conductors of the three-wire system would each be of a size and weight equal to $\frac{1}{4}$. So that the two-wire system would have a total weight of $2 \times 1 = 2$; and the total weight of the conductors for the three-wire system would be $3 \times \frac{1}{4} = \frac{3}{4}$. Or in other words, we would effect a saving of $1\frac{1}{4}$ out of 2, or $62\frac{1}{2}$ per cent. This saving is based upon the use of a neutral wire, whose size is identical with that of the main conductors, which, as we shall see later, is not always necessary, so that in practice the saving is about 70 per cent; or, in other words, the cost of the three-wire system of conductors in practice is about 30 per cent. of that of the two-wire system.

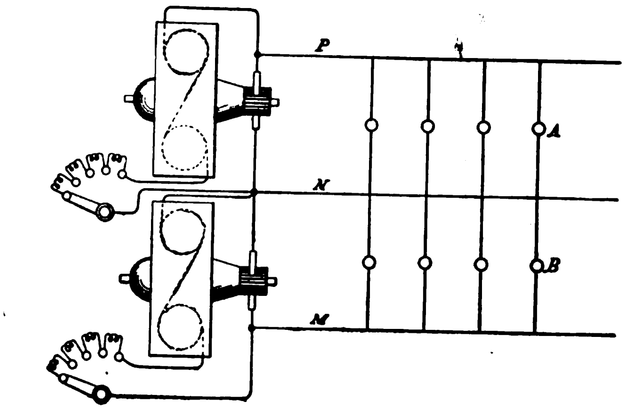

FIG. 2.

Many methods have been devised to accomplish the results obtained by Edison with his three-wire system, without the use of the divided source of electrical energy, and the compensating conductor connected to the point of division, but heretofore without success. The writer has recently however devised a system which accomplishes the same result in an independent manner.

Let us fix our attention upon the compensating conductor in Fig. 1 and Fig. 2, and see what happens to it when a single lamp is turned off. In the case of Fig. 2, a current of one lamp flows in the neutral, which had previously had no current flowing in it. In Fig. 1, *no* current flows in the neutral, but the potential of N changes. In Fig. 2, the potential of the neutral did not change, for its potential is constant by virtue of its connection to the point of constant potential between the two dynamos. It is usual considering these distributions, to consider the currents resultant upon the differences of potential, but I shall prefer to consider the potential of each wire as a more simple and direct method.

Let us suppose the potential of P to be 200, that of N 100, and that of M zero, so that we have a difference of potential or E. M. F. on both A and B of 100 volts. Also, let us suppose we have 100-volt lamps. Now evidently, since both dynamos on the three-wire system are machines of constant E. M. F. the conductors connected to their brushes will have constant potentials, which will be independent of the variations of the load on the two sides of the system, if we disregard the slight variations of potential at different points along the same conductor, which variations are no part of the present discussion.

By reference to Fig. 1, we find that the potentials of M and P will be constant and independent of the variations of load on both sides of the compensating conductor, but that the potential of N, the compensating conductor, will vary with every change in the load, so that the E. M. F. on A is sometimes higher than that on B and vice versa.

Evidently, the problem is, to keep the potential of N constant relative to the potential of M and of P, so that the difference of potential between N and the outside conductors,—that is, the E. M. F. on the lamps A and B, will be constant, as required by the lamps. One method of keeping the potential of N constant will be to connect to either of the constant potential conductors M or P a source of constant E. M. F. of 100 volts and connect the other pole of this source of constant E. M. F. to the compensating conductor N. This arrangement is shown in Fig. 3, where the source of constant E. M. F. is shown as being a battery, either primary or storage.

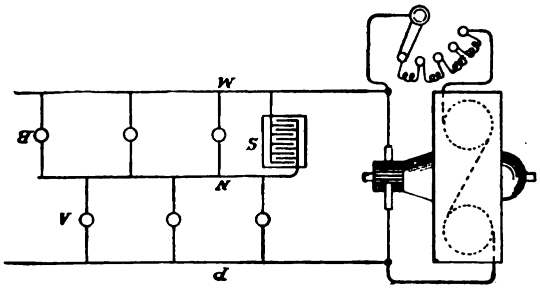

FIG. 3.

Another arrangement, Fig. 4, to accomplish the desired result will be to connect between N and one of the outside conductors M a dynamo, which is driven at a constant speed in a constant magnetic field; and hence, produces a constant E. M. F.

If the majority of the lamps are in group A the auxiliary generator C will operate as a motor, driving back upon and assisting the same engine that drives the main generator G. If the majority of the lamps are in group B, the auxiliary machine C becomes a generator and receives driving energy from the engine. If the lamps are evenly divided between A and B, the machine C will have no current through its armature, since the potential it supplies to N is exactly the same as the natural potential of N due to the fall of potential in the lamps between M and P.

Fig. 5 shows an arrangement in which a constant potential motor E drives the generator C at a point distant from the central station.

Fig. 6 shows a method of operating two towns or two sections of a town in series with each other, so as to secure the benefit due to the use of 400 volts for a distribution and yet have but one main generator, with three auxiliary generators of 100, 200 and 300 volts, respectively, supplying the necessary potentials to the three intermediate compensating conductors.

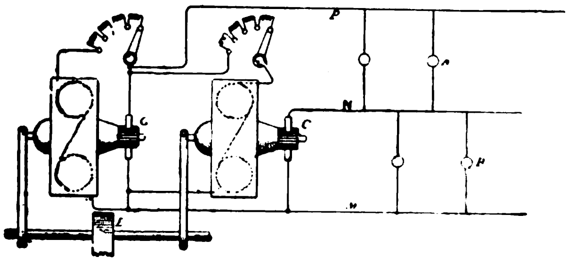

FIG. 4.

In practice in the use of this system, there is quite an advantage, due to the use of one large dynamo, for the small dynamo requires practically no attention. The field of the auxiliary generator is preferably excited separately from the main generator, so that the entire regulation of

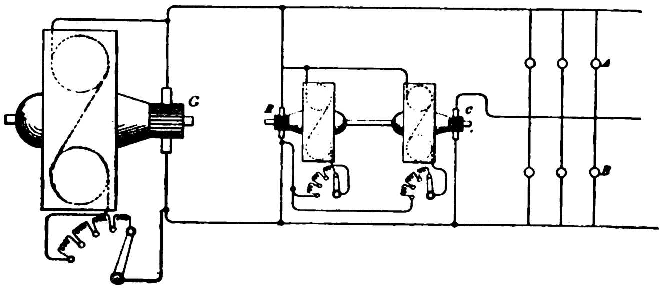

FIG. 5.

The average loss in the conductors of a three-wire system is about 40 per cent. of the loss under conditions of maximum load. If we pay consideration to the laws governing the plant is effected by the field regulator of the main generator.

As regards cost of installation, it is the general impression that under average conditions the first cost of a three-wire central station plant is greater than that of an alternating central station. This is, in reality, not the case, if the three-wire system be properly designed and the distances are those met with in usual practice. The question of first cost resolves itself into one of the cost of converters, versus the cost of three-wire feeders.

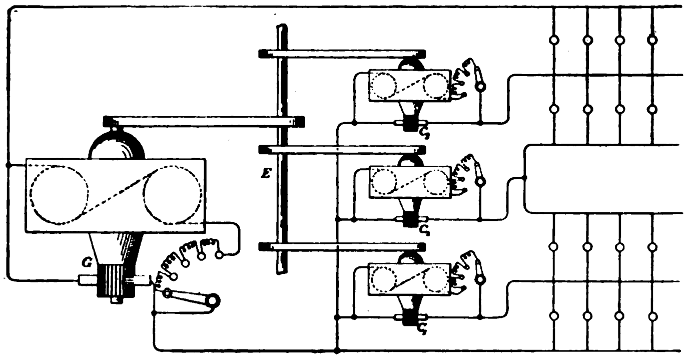

FIG. 6.

the proper loss in conductors, in order to realize a maximum economy, considering both interest on conductors and value of energy wasted therein, we shall find that, under any ordinary conditions, we should have an average loss of not less than 10 per cent.; otherwise, the interest on our investment in copper will be far in excess of the value of the energy which is wasted in them.

If our average load is 40 per cent. of the maximum, an average loss of 10 per cent. will correspond to a loss under maximum load of 25 per cent. In rare cases the average load will be 50 per cent. of the maximum, in which case the maximum loss should be 20 per cent., in order to have an average loss of 10 per cent.

The loss in the best converters, when fully loaded, is 4 per cent., and this loss is practically constant and independent of the load. Since the average load on the converters is 40 per cent. of the maximum, it is evident that the average loss in the converters, relative to the energy used in the lamps, is about 10 per cent.

In other words, the loss in a three-wire system varies directly as the load; whereas, in the alternating system, the larger portion of the total loss is constant and independent of the load. Hence, to secure the same average loss on the two systems, we must have a much larger maximum loss in the three-wire system than we do in the alternating system. But, as soon as we undertake to operate with a loss of 25 per cent. at full load, we find that a three-wire distribution presents engineering problems not at all simple, for we must not have a variation of pressure upon the lamps throughout the entire system exceeding two per cent., and to secure this uniformity of pressure, while effecting a total loss from dynamo to lamps of 25 per cent., involves the necessity of both engineering skill and experience.

The three-wire system is essentially the electrical engineer's system. The most perfect results possible are obtainable by its use, but, except when installed and maintained under guidance from an experienced electrical engineer, one of two results is certain. Either we will have a variation in pressure such as to give thorough dissatisfaction to the consumers, and an enormous expense, due to lamp breakage; or else we will have tons of unnecessary, unsightly and superfluous copper, which means sure death to any extension of the system, involving, as it does, an amount of copper increasing as the square of the distance.

Many a good central station plant, installed on the three-wire system, is to-day a monument to the plausible theory, so conspicuously fallacious in electrical engineering: "Make it large enough. It cannot be too large." Instances are common in this country where a limited territory, near the station, was wired for a maximum loss of, say, 10 per cent. The cost of copper was quite moderate, perhaps one dollar per lamp. On account of a lack of proper electrical engineering, the system soon showed a variation of five volts, with corresponding increase in the lamp breakage. Now the fatal mistake was made of putting in more copper. The maximum loss is reduced to perhaps 5 per cent., and the cost is still not excessive, being only two dollars per lamp. But a standard has been fixed, which is entirely uncommercial, and all progress in the development of the system is blocked by the useless additional copper purchased and installed on the rule-of-thumb method.

In nine-tenths of the three-wire systems in this country the area covered by the system and the capacity of the system of conductors can, by accurate electrical engineering work, be doubled, without buying an additional pound of copper beyond that already in use, and with a loss in conductors not exceeding that demanded by the considerations of best economy.

But few people realize that, with 110-volt lamps, on a three-wire system, having a maximum loss of 20 per cent. or an average loss of 8 per cent. the cost of copper is only two dollars per lamp, when the system covers a territory one mile in every direction from the station. With such a loss in distribution any commercial centre can be covered by a three-wire system, at a cost no greater than that of the alternating system, and often much less; and it presents strong advantages at present, on account of its applicability for motive power as well as light.

The alternating system, however, presents advantages on account of its simplicity, both in installation and operation, which make it far preferable to the three-wire, in cases where a system is to be installed and extended, without electrical engineering advice. To economically supply the requirements of a general electrical distribution in a town, both the three-wire and alternating systems are at present essential, and since both systems can now be supplied by a large number of different concerns, there is no reason why future central stations should not have all the advantages of both systems.

"THE BEST."

A SUBSCRIBER at West Lynn, Mass., writes us: "I consider THE ELECTRICAL ENGINEER the best magazine of electrical science yet published."

IRON PIPES FOR INTERIOR CONDUITS.

BY

Fremont Wilson

Two and a half years ago the writer was asked for an opinion in regard to interior conduits, and to the surprise of the party asking the question, he said: "Interior conduits to be successful must be able to stand the action of all kinds of alkali in plasters, and must be absolutely proof against the tools of mechanics, and, furthermore, absolutely waterproof and fireproof, and must *not* be relied upon for *insulation, the only place for insulation being upon the conductors themselves.*" The question was then asked: "Why, then, do the New England Underwriters insist upon the use of conduits, and furthermore, allow the use of such cheap grades of wire? The reply was, that any party or parties who recommended any conduit then on the market, or demanded its use, and allowed twin conductors with cotton insulation, was either ignorant of the entire subject, or was interested; for the only conduit that was needed was that used by the gas man, viz., iron pipe, to be made and installed under certain specifications. The writer also had the word of one of the largest pipe-makers that a first-class article of piping with right and left threads could be placed on the market at the same price as gaspipe, and perhaps cheaper; but the trouble with this system was, simply that it could not be patented, and therefore, underwriters, architects, and owners of buildings must be kept in blissful ignorance of the safety and feasibility of iron conduits so as to enable conduit people to line their pockets with the money of the poor public.

For this answer the writer was severely criticised by certain parties, but, nevertheless, time has proved that the remarks were correct, inasmuch, as, at the Convention held at Buffalo in February of this year, Capt. Brophy, formerly of the Boston Insurance Exchange, was forced to admit that the conduits used were a failure.

The writer over two years ago installed in New York an installation of over 3,000 lamps, and all the primary feeders connecting the various converters were placed in gaspipes. The pipes were laid on the iron ledges of the building and white core taped wire used; and, although these pipes and wires of a total length of about two miles were placed in position by inexperienced men, yet they have been in constant successful use for eighteen months, conveying a current of 15 amperes and 1,000 volts, constantly exposed to the weather; and yet we hear that it can't be done—that to install iron pipes and pull in wires for use at 50 or 100 volts pressure would be suicidal. Is not every combination gas fixture an example of conduits?

That the conduit people have seen their blunder is only too evident as we all know, from the fact of their covering their present material with metal; but let us hope that before long the underwriters will not only *allow*, but *insist* on, solid metal conduits specially built and installed in all classes of concealed work, and then, and not till then, will this everlasting hue and cry about electric light fires cease.

The New Orleans Underwriters have just adopted a stringent rule in regard to conduits, but they are simply recommending a special conduit, although it does not show on the face of their order, and they will go through the same experience, only in a less degree, that the Boston Underwriters have passed through. There is, in the writer's judgment, but one conduit; and let us learn a lesson from our enemy, the gas-man, and use it—the iron one. I may add that the Chicago Underwriters have recently stated that they are in favor of iron conduits; and the question must soon be faced by all concerned.

NOTES ON THE DETERMINATION OF WIRE FOR MULTIPLE ARC DISTRIBUTION.

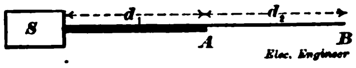
BY

H. Robinson Wellman

WHILE Mr. Woodbridge[1] has given us some instructive and interesting formulæ, they are not readily adaptable owing to the form in which he has left them. By going a little farther we can deduce from them others, equally interesting, and of far greater practical value. Taking the familiar formula

$$C.\,M. = \frac{10.3 \times C \times D}{V} \qquad (1)$$

and the case assumed by Mr. Woodbridge in Fig. 4 of his article as shown below, viz.:



Current consumed at A $= a_1$,
" " " B $= a_2$,

together with his deduction (the denominator of which I have taken the liberty of changing, thinking it must be a typographical error, and substituting $\frac{C.\,M.}{k}$ for W, we have

$$\frac{C.\,M._{\text{S. A.}}}{C.\,M_{\text{A. B.}}} = \frac{\sqrt{a_1 + a_2}}{\sqrt{a_2}} \qquad (2)$$

from (1)

$$\text{loss}_{\text{S. A.}} = \frac{10.3 \times d_1 \times (a_1 + a_2)}{C.\,M._{\text{S. A.}}} \qquad (3),$$

$$\text{and loss}_{\text{A. B.}} = \frac{10.3 \times d_2 \times a_2}{C.\,M._{\text{A. B.}}} \qquad (4)$$

(3) and (4)

$$\frac{\text{loss}_{\text{S. A.}}}{\text{loss}_{\text{A. B.}}} = \frac{\dfrac{10.3 \times d_1 \times (a_1 + a_2)}{C.\,M._{\text{S. A.}}}}{\dfrac{10.3 \times d_2 \times a_2}{C.\,M._{\text{A. B.}}}}$$

$$= \frac{d_1 \times (a_1 + a_2)}{d_2 \times a_2} \times \frac{C.\,M._{\text{A. B.}}}{C.\,M._{\text{S. A.}}}$$

Substituting from (2),

$$\frac{\text{loss}_{\text{S. A.}}}{\text{loss}_{\text{A. B.}}} = \frac{d_1 \times (a_1 + a_2)}{d_2 \times a_2} \times \frac{\sqrt{a_2}}{\sqrt{a_1 + a_2}}$$

Reducing

$$\frac{\text{loss}_{\text{S. A.}}}{\text{loss}_{\text{A. B.}}} = \frac{d_1 \times \sqrt{a_1 + a_2}}{d_2 \sqrt{a_2}} \qquad (5)$$

∴ The loss should be proportional to distance × $\sqrt{\text{current}}$.

Let $V =$ total loss $= \text{loss}_{\text{S. A.}} + \text{loss}_{\text{A. B.}}$.

Then, $\text{loss}_{\text{A. B.}} = V - \text{loss}_{\text{S. A.}}$. Substituting in (5),

$$\frac{\text{loss}_{\text{S. A.}}}{V - \text{loss}_{\text{S. A.}}} = \frac{d_1 \times \sqrt{a_1 + a_2}}{d_2 \times \sqrt{a_2}}$$

$$\therefore \text{loss}_{\text{S. A.}} = \frac{V \times d_1 \times \sqrt{a_1 + a_2}}{d_2 \times \sqrt{a_2} + d_1 \times \sqrt{a_1 + a_2}} \qquad (6)$$

$$\text{and loss}_{\text{A. B.}} = \frac{V \times d_2 \times \sqrt{a_2}}{d_2 \times \sqrt{a_2} + d_1 \times \sqrt{a_1 + a_2}} \qquad (7)$$

(6) and (7) are, I believe, the most convenient forms in which they can be left, as they tell us how to proportion our *losses*, and leaves us free to use any formula, chart or other method that we may prefer, with which to calculate our millage; though we could continue and produce formulæ giving us the area direct, without the determination of the losses. The same reasoning applied to Mr. Woodbridge's second deduction gives,

$$\frac{\text{loss}_{\text{S. A.}}}{\text{loss}_{\text{A. B.}}} = \frac{d_1}{d_2}; \text{ from which we get } \text{loss}_{\text{S. A.}} = \frac{V d_1}{d_1 + d_2}, \text{ and}$$

$$\text{loss}_{\text{A. B.}} = \frac{V d_2}{d_1 + d_2}.$$

THE APPLICATION OF LOGARITHMS IN CALCULATING SIZES OF ELECTRIC CONDUCTORS.

BY

Thos. J. Fay

FEW indeed are the problems to which logarithms may not be applied to advantage. In the solution of problems involving involution and evolution they are indispensable. However, with practice, so that one can handle them quickly, the ordinary calculations involving multiplication and division may be handled quickly and accurately, and that too, with a great reduction of mental labor. In fact logarithms may well be called "the lazy man's method." Those engaged in laying out wiring plans, know well the tediousness of such an undertaking requiring, as it does, many repetitions of the same formula. No doubt the monotony of the work makes it such that errors are liable to creep in, purely from that cause.

The method of applying logarithms in this case differs in no way from that of the ordinary or Briggsian method. Any table of common logarithms may be employed. In the following table the logarithms are those of the constants for given losses in volts, and are used as shown in the formula:

Volts loss.	Log.	Volts loss.	Log.
1	1.326541	6	0.547775
2	1.025806	7	0.481443
3	0.849419	8	0.423246
4	0.724276	9	0.369216
5	0.627366	10	0.326336

log 4 = 0.602060.

FORMULA.

$\log d^2 = \log C + \log D + \log V$, for 2-wire system.
$\log d^2 = \log C + \log D + \log V - \log 4$, for 3-wire system.
$d^2 =$ area in circular mils.
$C =$ current in amperes.
$D =$ distance in feet from source of supply to delivery.

Example.—It is required to find the area in circular mils of a conductor which will carry 100 amperes of current 800 feet, with 4 volts loss.

Solution.—Log 100 = 2.000000.
" 800 = 2.903090.
" V = 0.724276.
" d^2 = 5.627366, for 2-wire system.
" 4 = 0.602060.
" d^2 = 5.025306, for 3-wire system.

This calculation is explained as follows:

The number represented by log 5.627366 is 424,000, which is the required area in circular mils for the 2-wire system. The number represented by log 5.025306, is 106,000, which is the required area in circular mils for the 3-wire system.

Heating Effect.—It will be remembered that wiring formulæ are not always applicable; that is, the area of the wire as found is insufficient in many cases to carry the current without undue heating. After computing the size of wire by formula it is always essential that it be compared with some standard for *safe-carrying capacity.*

The following method by logarithms may be found easy to work; the result has been practically tested, and is known to be correct:

$$\log C = \frac{(\log d \times 3) - 3.397940}{2}$$

d = diameter of the conductor in mils.

C = current in amperes.

Example.—It is desired to find the safe-carrying capacity of a wire 460 mils in diameter.

$$\begin{array}{rr} \textit{Solution.}\text{—Log } 460 = & 2.662758 \\ & \underline{3} \\ & 7.988274 \\ & \underline{3.397940} \\ & 2\overline{)4.590334} \\ \log C = & 2.295167 \end{array}$$

The number corresponding to log 2.295167 is found to be 197.31. Hence, 197.31 amperes is the safe-carrying capacity.

It is assumed in working these problems that the conductors are of 96 per cent. conductivity and that they will heat 30 degrees Fahrenheit over the surrounding temperature when covered with average rubber insulation taped and braided. The specific resistance is taken at 75 degrees Fahrenheit.

SOME ABNORMAL EARTH CURRENTS.

BY

D. B. Grandy

I have recently encountered phenomena in the domain of earth currents which varied somewhat from the ordinary manifestations with which I am familiar, and an account of which may be of interest.

One of the lines of the Postal Telegraph-Cable Co. carrying three wires, traverses a section on the east bank of the Mississippi, between Venice and Alton, Ill., which was inundated during the recent flood. At one point, about 10 miles from St. Louis, two poles were washed out and two of the wires were broken and fell into the river. The third wire pulled out its pins and remained intact, spanning the break in the pole line, and clear of the water. On grounding the two broken wires at the St. Louis office, a current was formed of sufficient strength to work the instruments on both wires. The current was negative in polarity, with an E. M. F. of about 13 volts, as shown on a voltmeter. The current remained steady, with no perceptible fluctuation for several days, until the wires were taken out of the water and restored to their normal condition. During that time the two broken wires were kept open at Alton, beyond the break; the only "live" wire within three miles of the break was the third wire on the same line, the opening of that at Alton did not affect the current on the other two wires in the least; so that there would seem to be no doubt about the current in them being an earth current.

We have another instance of a permanent earth current in one of our city wires. The wire extends about five miles to a point in the southwestern part of the city where it is "grounded" on the water pipes in a manufacturing establishment, several blocks away from any electric railway or line of telegraph wires. On grounding this wire at the main office, a negative current with an E. M. F. of 15 volts shows itself. This current has remained at its present strength for over five years, and fluctuates but little. The current is amply sufficient to work the wire without the use of any battery.

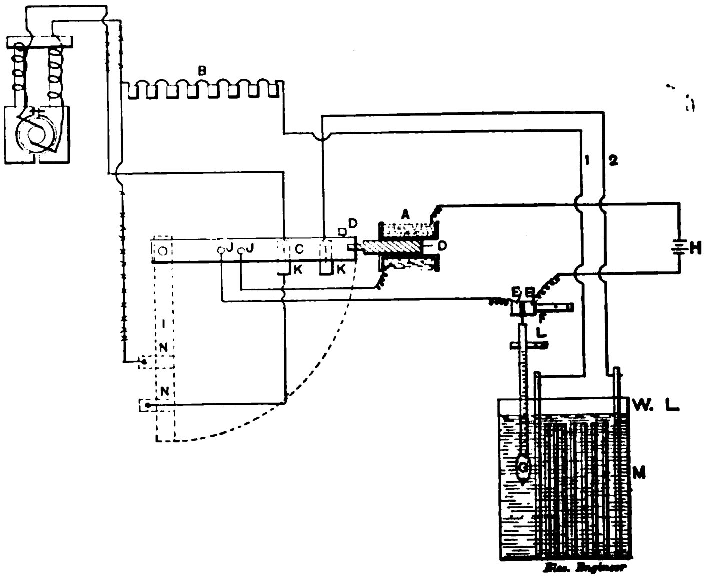
In many other wires the earth current is found to be appreciable on an ordinary relay, but does not approach the instances cited in strength or permanence.

PEARSON'S AUTOMATIC STORAGE BATTERY CUT-OUT AND SWITCH.

BY

J. J. Pearson, E. E.

In installing secondary battery plants one of the chief difficulties the engineer encounters is the trouble in instructing the attendant in the use of the hydrometer to determine the amount of the charge. An incident of this kind suggested an arrangement which the writer constructed about a year ago, and which has since proven to work very satisfactorily, being very sensitive and positive in its action. One cell of the working plant, as shown in the accompanying diagram, is extended by means of the wires 1, 2, to a suitable shelf or case so as to retain its original position in the circuit. A hydrometer G bearing a cap of aluminum, and contact pin F is suspended in a perpendicular position by means of the support L, in which it moves freely and also acts as a guide to the terminals E E, which should be made so as to be adjustable to a higher or lower position. The operation is as follows:



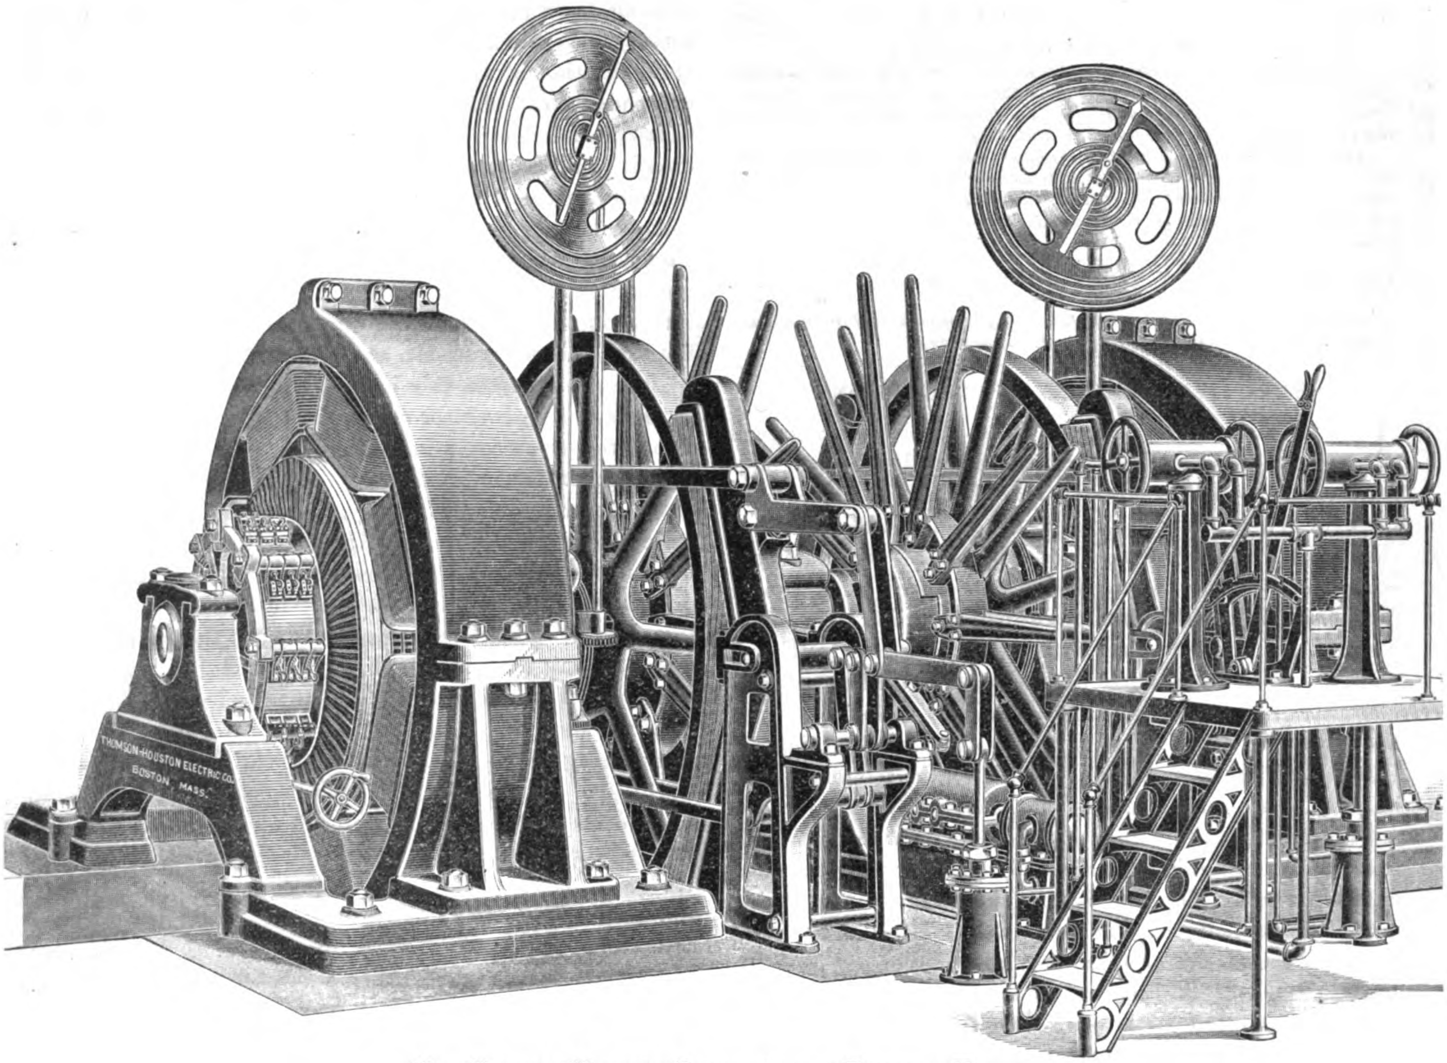
Pearson's Storage Battery Cut-Out and Switch.

The switch bar C, being thrown up in its position for charging, is locked in this position by the lug in the end of the movable core D, acting in solenoid A; this throws the charging current at K K through battery B, which continues as long as the hydrometer is below the proper density point. But when the solution reaches the proper density the hydrometer rises, closes the local circuit at E E, which pulls out the lug at the end of the movable core D, engaging the end of bar C and allowing it to drop by gravity or spring, cutting out the battery and throwing in lamps or resistance at N N. This same operation opens the local circuit J J. The instrument remains in this condition until discharged, and the bar C is again thrown into position.

The cell M should have a thin film of oil poured over the solution to prevent evaporation, and care should be taken to always have the solution at the proper height by means of water lines W L.

NEW THOMSON HOUSTON DIRECT-ACTING ELECTRIC HOISTS.

The rapid hoisting of heavy loads from deep mines by the direct application of the power to the reel shaft without the intervention of gearing, offers the most favorable conditions for the use of the electric motor in hoisting work. Much greater economy can be shown in the use of power, while a high hoisting speed can be safely and easily attained—a matter of importance where large quantities of ore are to be handled. Having in mind the fact that gearing has its limits, both in speed and safety, the Thomson-Houston Electric Co. have just brought out a new direct-acting electric hoist designed in general to operate with flat wire rope. The hoist, which is shown in the accompanying engraving is operated by two M. P. type motors, one on each end of the reel shaft, each capable of developing 500 h. p., or having a combined output of 1,000 h. p. This hoist is designed to raise a load of 10,000 pounds from a depth of 2,500 feet in one minute. Of course, for hoisting and lowering men, or for other purposes, any desired speed can be obtained at the will of the operator. Lowering can be done under complete control of the motors and without the use of the brakes when desired. Post brakes of a very powerful and effective type are used, being drawn together by rods above and below the reel shaft, so that all parts move in parallel lines, distributing the wear equally on the brake shoes and applying the pressure at two points in each shoe equally distant from the centre. The shoes are also pivoted at the centre, so as to quickly adjust themselves to the faces of the brake wheels. The clutches are of the jaw type, that portion of the shaft upon which they slide being hexagonal in form. Both clutches and brakes are operated by cylinders using compressed air, a small air compressor driven by an electric motor placed at the centre of the hoist supplying air for this purpose. The compressor requires no attention whatever, being automatic in its action; stopping when the pressure in the receiver forming its base reaches a certain point, and operating entirely independent of the hoist. Two sets of valves, actuated by hand wheels, one for the brake and one for the clutch, are placed convenient to the operator on each side of the centre of the hoist, each set controlling the brake and clutch on its side.



THOMSON-HOUSTON ELECTRIC CO.
BOSTON, MASS.

New Thomson-Houston Direct-Acting Electric Hoists.

The brake wheels, reels, etc., are, as will be seen, of the usual form, the brake wheel being keyed to the hub of the reel, which runs loose upon the shaft when not in clutch. The reel hubs are bushed with hard composition, means for their thorough lubrication and easy removal being provided.

Dial indicators operated by worm gears on the reel hubs are attached to each reel, showing the position of the cage in the shaft. All levers are arranged within easy reach of the operator, so that one man can attend to both reels and brakes without difficulty.

Only about one-half the space of steam hoists of the same capacity is occupied, insuring a great saving in buildings and foundations alone, while the well-known economy of the electric motor in the use of power makes its application to direct-acting hoists requiring large power of the utmost importance in a commercial sense. We may add that these hoists are built in sizes from 500 to 3,000 h. p.; the largest being capable of lifting a weight of 32,000 pounds from a depth of 3,000 feet at a speed of 3,000 feet per minute.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

VOL. XIII. NEW YORK, JUNE 8, 1892. No. 214.

No man can learn what he has not preparation for learning, however near to his eyes is the object.—Emerson.

SELECTIVE SIGNALS IN TELEPHONY.

EVER and anon, branches of an art which have remained in a quiescent state are suddenly called into prominence, and the most recent example of this is to be found in the field of telephony. Many of our readers will remember that shortly after the telephone became a practical and commercial success the need was recognized of a simple device which would enable more than one subscriber to be placed upon a single line without interference with one another. Yet after nearly fifteen years of trial and experiment the fact remains that "individual calls" have not been introduced. Even with all the other needs which are still the subject of work and speculation in telephony, we believe we are safe in saying that there is no more important requirement to be filled in this field than the introduction of a thoroughly reliable and commercially practical individual call. The time is not far distant when, in our large cities at least, it will become a matter of absolute necessity to place more than one subscriber on one line. To state the case in another way it is problematical whether if the number of subscribers in New York City were raised from the present number to three times that number, or say thirty thousand, the telephone business would be a paying one at the rate charged at present. The individual call would be one great factor, though not the only one, it is true, in handling a business of this magnitude effectually; and hence it would be well for electricians to devote their serious attention to the solution of this problem. Mr. Thomas D. Lockwood deserves the thanks of all workers in this field for the admirably clear and succinct manner in which he has presented a digest of the state of the art of individual signaling, in his paper read before the American Institute of Electrical Engineers, at Chicago. As he puts it, much time has been wasted by inventors in the past, owing to a lack of knowledge on their part of telephone work done in this department, in which alone no fewer than one hundred and sixty-one patents have been issued in this country. Besides that, however, he points out what ought to be avoided and what is essential to a successful instrument of this type,—information which many have long sought at great sacrifice of time and money.

LEONARD'S THREE-WIRE SYSTEM.

THE distribution of current viewed from the standpoint of economy in copper has from the first been the study of all electrical engineers, and was naturally forced more particularly on those who chose the methods of low tension distribution. Even Mr. Edison, who has always advocated putting down plenty of copper, saw the limitations which a two-wire system placed upon low tension distribution, and the evolution of the three-wire system was the natural consequence of a demand for a method which, while permitting each lamp or other "translating device" in the circuit to be manipulated independently of every other and at its original low potential, still allowed of an appreciable reduction in copper. The practice inaugurated by Mr. Edison has since been adhered to almost without a single modification, except in detail, and hence it is all the more interesting to note a departure in this method of distribution as proposed by Mr. H. Ward Leonard and described by him elsewhere in this issue. Mr. Leonard shows how by means of a generator connected to the two outside wires of a three-wire system in conjunction with a smaller auxiliary generator or motor as the case may be, the current in the neutral wire can be taken care of and the system be maintained in equilibrium. Incidentally Mr. Leonard also points out a few considerations of the highest importance in the designing of a three-wire system, and shows how in the effort to reduce the losses on a part of the system the remainder may be seriously affected. If Mr. Leonard's bold statement that nine-tenths of the three-wire plants in this country could be doubled in capacity by good electrical engineering is true, then there is a field here alone which might give our electrical engineers work for a long time to come without the need of looking for new fields to conquer. We fully agree with him, nevertheless, that the three-wire system is still open to vast extension and improvement, and need only recall to our readers the excellent work now being done in Brooklyn, N. Y., by Mr. W. S. Barstow, an account of which has already appeared in these columns.

GOVERNING STEAM ENGINES ELECTRICALLY.

As the electric art advances, engineers are constantly brought face to face with imperfections in the older types of machinery which are employed as auxiliaries, of which the steam engine is probably the most conspicuous example. Much has already been done towards the improvement of the steam engine as a prime mover, especially in the direction of its regulating properties. This was justly deemed necessary in the early days of electric lighting, where the slightest inequality in the speed showed itself perceptibly in the character of the light; but regulation has more recently become a matter involving, not merely a question of smoothness in working, but also of economy. It was early suggested that electromagnetic apparatus might be emlpoyed for the regulation of engines driving electric machines, and several devices of this nature will be recalled by our readers. They consisted almost without exception in throttling governors, and were, in consequence, but ill adapted to the finer regulation and economy desirable. In investigating the methods by which the best results in electric governing can be obtained, Mr. Wm. S. Aldrich, of the Johns Hopkins University, in a paper read before the American Society of Mechanical Engineers, at its San Francisco meeting, points out that an electromagnetic mechanism under control of the turning movement of the dynamo, or of its external electric circuit, can be used by introducing the dynamometer governing principle, while the centrifugal governing power may be introduced to control the engine when there is no load on the dynamo. By employing a "rotary-piston" valve, a compound movement may thus be obtained by giving the centrifugal valve governor control of the reciprocating, and the electromagnet mechanism control of the rotary movement. It is evident that a variety of forms of apparatus is open to the electrical engineer for carrying out this method of compound governing. With a valve so controlled the distribution of steam on a multiple expansion engine, for electric railway service, for instance, could be controlled in a manner far better than is now done with the centrifugal governor alone. It is also apparent that with such a system of governing the weight of the fly-wheel necessary to obtain the necessary uniformity of speed might be considerably reduced. We hope that Mr. Aldrich may succeed in having the ideas put forward by him carried out in a practical way, as the method suggested seems well worthy of a fair trial.

THE VALUE OF CONDUITS FOR WIRES.

An article by Mr. Fremont Wilson in our columns this week describes on installation made by him in this city of over 3,000 lights, in which the wires are carried through iron pipe. The plant has been very successful, he says, and he comes out therefore as a strong advocate of solid metal conduits. The fact recorded is very interesting, and it would seem that iron pipes have an important place in electric lighting economy, but we cannot follow Mr. Wilson in his attack on interior conduits of the type with which we are now all familiar. There are two or three such now before the public, and the manufacturers of one of them at least deserve all the benefit they can get from the indisputable fact that they were first and foremost in promoting the plan of "piping" the electric light wires. We have always looked upon that as one of the greatest advances made in incandescent lighting, and we believe the time is rapidly approaching when interior wires will be run through tubes only, and will not be permitted to ramify in any other way in any building whatsoever. As to the patent side of the question, it seems only natural that in developing tube systems, ideas and methods of great value, if covered by patent, would be developed; and if that is the case, it is to be hoped that in this field as in every other where the inventor works, the patentees will be able "to line their pockets with the money of the poor public." We are only at the beginning of incandescent lighting, and therefore everything that will add to its convenience, safety and flexibility is to be encouraged. That there should be a fight, and a vigorous one, for the control of new and valuable features of wiring is only natural, but we must confess that our sympathies are with the men who spend time, money and brain power in perfecting those features rather than with the people who want to use them for nothing. Mr. Wilson is of the opinion that he has hit upon one method free from patent royalties. If so, no one is injured.

LIGHTING THE WORLD'S FAIR.

Reference was again made in these columns, last week, to the contract secured by the Westinghouse Electric and Manufacturing Co. to furnish the incandescent lighting for the World's Fair, and to the large amount of the bond required from Mr. Westinghouse, namely, $1,000,000. It is now reported from Chicago that Mr. Westinghouse has gone to that city to obtain, if possible, a reduction in the amount of the bond, and that he is quite willing to stake $500,000. While it is most essential that the lighting should be a sure thing, we cannot but feel that the terms have been made unduly onerous, and that Mr. Westinghouse is right in his contention. If bonds of this magnitude were asked every time a plant of 5,000 or 10,000 h. p. was required, electric light and power would not make anything like the headway they are now doing. We may be wrong, but the prices of the contract are so low that for that reason alone the Westinghouse Company ought to receive generous treatment. It certainly stands to make very little out of the contract, probably nothing except "the ad. there is in it," which is very much like the benefit derivable from bill posting; and the company is therefore entitled to the consideration due a low bidder under the circumstances. The price, if we are not mistaken, now stands just short of $400,000. For that sum Mr. Westinghouse will be called upon to furnish 83,410 incandescent lamps of 16 c. p. each and 6,212 lamps of 10 c. p. each, making a total of 89,622 lamps. In addition he will furnish 8 arc lamps of 2,000 c. p. each, which will be installed in the dome of the Administration Building. Can anybody else be very anxious for the contract at that price?

SPARKING AND FLASHING IN DYNAMOS.

In a paper read before the Chicago Electrical Association on the above subject, Mr. F. R. McBerty has analyzed the actions which take place in the passage of a generating coil on the armature and showed how the ideal non-sparking conditions are modified by disturbing actions. Taking for an example a Gramme wound armature, Mr. McBerty pointed out, how the self-induction of the armature acted to cause flashing upon a change of load, and the difficulties it introduced in effecting regulation. One method of overcoming the difficulty is to employ a brush are rather a multiple brush covering a portion of the circumference of the commutator; in that case the brushes must be placed a little forward of the neutral line, in order to fulfil the conditions necessary to prevent sparking. Mr. McBerty's paper presented the subject in a very clear manner and we remark that in the new edition of "Dynamo Electric Machinery," Prof. Sylvanus P. Thompson adopts a similar method of explaining the phenomena of sparking.

SELECTIVE OR INDIVIDUAL SIGNALS.[1]

BY THOMAS D. LOCKWOOD.

THE USE OR FUNCTION OF SELECTIVE SIGNALS IN TELEPHONY.

THE business of the average user of the telephone keeps a line employed but for a very small part of the entire business day, and for the remainder of the time the line wire is idle and earning absolutely nothing. If by any means it could be made possible to place several sub-stations in connection with the same circuit, without materially affecting the efficiency of the service rendered, it is obvious that the earning power of the circuit would be largely increased. But a call-bell or other signal is clearly necessary in order that the attention of the station may be attracted when some other station desires to communicate, and as we add stations to a circuit we also necessarily add call-bells; thus introducing two practical objections, viz:

1. A most incessant and annoying ringing, because a call sent to any station is heard at all stations.
2. The necessity of distinctive signals, whereby when the bell at any station is rung the attendant may know whether the call is for his or for some other station.

At this juncture the selective signal steps in, and its special work or function may be thus stated: That two or more stations being electrically connected with the same circuit, the call-bell at any predetermined or desired one of such stations may be operated, and the call given there, to the exclusion of the call-bells at the other stations, which at the same time remain quiescent, or are silent.

This statement of function justifies the term "*selective signal*" which I have adopted, and which I conceive to be more appropriate than the old term "individual signal" because more descriptive.

HISTORICAL SKETCH OF SELECTIVE SIGNALS.

The idea of producing a practical selective signal is not (as might from the introductory remarks of this paper have been supposed) one which made its first appearance subsequent to the advent of the telephone.

Appliances possessing the same characteristics appeared in England many years ago, and several forms have from time to time been patented in this country for use in connection with telegraphy, which closely resemble some of the forms which within the last 10 or 12 years have been reinvented and patented here.

One of these[2] is based upon combinations of a plurality of line wires, two or more of which extend from a terminal to each two sub-stations.

A second[3] involves two wires together with the use of both directions, and varying strengths of current; and states itself to be "for sounding any particular alarm in a set of telegraph stations."

The third,[4] quoting from the published abstract, is for "transmitting secret intelligence to any one or more stations without the use of extra wires. At each station a metallic disc, suitably inlaid with non-conducting portions, is brought to the required position in order to complete the circuit or not, by any electromagnetic step-by-step movement, thus excluding or including the telegraph instrument at any particular station or set of stations as required."

Three other British patents prior to 1876 are of this class, [5, 6, 7] one of which[5] speaks of "an apparatus comprising a main line, a series of independent branch or station lines at each end, and clocks at both ends working synchronously, which, by means of revolving cams, place the main wire in consecutive connection with corresponding branches at the two ends for definite times."

In France, too, in connection with railway telegraphy, this class of invention was formerly very popular; and as might be expected, is not neglected by that indefatigable chronicler, the late Count du Moncel, who devotes considerable space to the subject in the *Exposé des Applications de L'Electricité*.[8]

In the plan of Lamothe, for example, which is discussed by M. du Moncel, the gong which is to be struck is by one electromagnet brought within range of a bell hammer, which then by a second electromagnet is caused to strike the bell.

Another inventor, Bizot, has a plan for selectively ringing bells by means of pendulum hammers placed at the different stations, and adjusted at each station to a different length.

An electromagnet at each station in the main circuit controls the swing of the pendulums by its alternate magnetizations and demagnetizations brought about by the makes and breaks of the main line current; these being effected by a vibratory circuit breaker at the transmitter station, operated by a similar electromagnetic pendulum there, which can be adjusted when desired, to the same length as the pendulum at any one of the other stations which it is desired to operate. Only that one to which it is adjusted, will be operated; the others remaining inert. By so arranging *all* of the station pendulums that they can be adjusted, any station is enabled to selectively signal any other.

This apparatus I have described at considerable length, because it is founded on the harmonic principle which later was introduced into telegraphy, and because it contemplates the use in selective signaling of that principle, subsequently more elaborately worked out by German and American inventors and described in their several patents.[9]

Martorey's system, which likewise is described by M. du Moncel, also contains the elements of many subsequent forms. In it, by an electromagnetic step-by-step motion, an escapement wheel having a number of teeth at least equal to the number of stations on the circuit, to give the signal, is brought to a given position by a given number of pulsations, differing for each station. All the teeth are metallic, and all, except one, are insulated.

In addition to the foregoing examples of the condition of the art, it is not, I conceive, out of order to point out that the principles which govern printing telegraphy are closely related also to selective signaling. Consider, for example, the House, Hughes and Phelps telegraphs, and the form of stock quotation recorders now so universally employed; in all of these a given letter or figure is brought to a suitable point and is then pressed by a final operation against the paper to make the impression.

A good stock of knowledge thus was at the disposal of those interested, even at as early a date as 1876, when the career of the telephone was only beginning. We had the electromagnetic ratchet and pawl, step-by-step movement. We had electrically controlled clock-trains.

Why then was it not easy to make at once a thoroughly satisfactory and efficient selective call? One reason is, that the average inventor or would-be inventor generally refuses, tacitly, it is true, to recognize that there is any material of which he may make use. He does not know the state of the art.

From January, 1879, to December, 1891, 161 U. S. patents were granted for forms of Telephonic Selective Signaling appliances, all of which I have examined. A careful analysis shows that quite a large number of general plans have been proposed, and that each of these has been developed in several ways, with greater or less care, and to many degrees of perfection. Several sub-methods can be utilized in many of the general plans, and in a number of cases attempt has been made to provide for several additional functions. Though at one or two points selective signals embodying a few of these different plans are even yet employed, every telephone man knows that it cannot truly be asserted that success has attended such appliances.

DESIRABILITY OF SELECTIVE SIGNALS.

This epigrammatic saying is, however, in some sort losing its attractiveness, in face of the multitude of conductors which it implies; and to a keen observer of the signs of the telephonic times, it is evident that a very extensive return to party lines in some form will, bye and bye, be inevitable; at all events for residential districts, and from this point of view it appears that the demand for a simple and trustworthy, but not costly, selective signal is as great as ever, and that, if such a thing is made, and its merits proved, many more party lines could and would be arranged and satisfactorily operated.

And to aid the adventurer who intends to construct such an apparatus, I will outline the principles upon which this class of work in its several proposed plans have so far been founded, reference being made in brackets to a single U. S. patent exemplifying each of the several plans.

GENERAL PLANS.

1. *To operate the several signals at each sub-station on a circuit with differing strengths of current.*

Bells depending for their proper operation on a margin of current are, however, generally untrustworthy. [U. S. Patent—No. 221,512, Nov. 11, 1879, Buell.]

2. *Signals arranged to respond to currents of opposed direction.*

This implies, of course, polarized bells, and for a line with but two stations, it is probably as good an arrangement as can be provided. [U. S. Patent—No. 218,153, August 5, 1879, Anders.]

3. *Signals involving changes both in strength and direction of currents.*

These are apt to be unreliable for the same reason as are those of No. 1. [Patent No. 242,408, May 31, 1881, Anders and Vail.]

4. *Electromagnetic step-by-step devices, acting to bring the sub-station signals to a ringing point differing for each section, and then to close a local, branch, or shunt circuit, including the local*

U. S. Patent 251,097, Currier, December 20, 1881, and others.

bell, to operate ringing mechanism, or in some way to introduce the bell magnet into the circuit.

Fig. 1, taken from a patent of E. N. Dickerson, Jr., illustrates a ratchet and pawl step-by-step movement operating to close a local circuit in which is placed the bell. Successive pulsations sent from the central station, cause the electromagnet M in the main line circuit to attract its armature *a*, which after each pulsation is pulled back by a suitable spring (not shown).

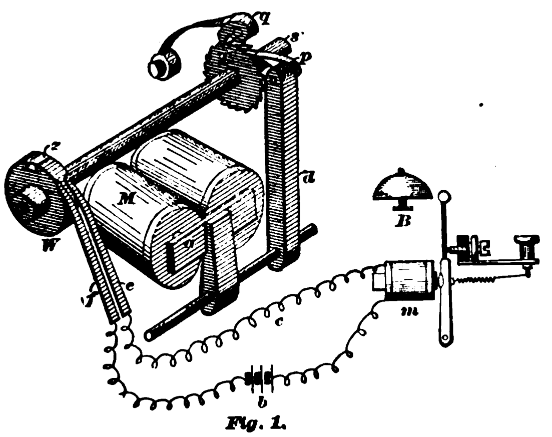

Fig. 1.

The non-conducting wheel *w*, on which presses the two springs *e* and *f*, has at one point on its periphery an inlaid piece of metal *z*. When the wheel is rotated till the plate *z* comes under the two springs, the local circuit of the battery *b* is closed through the bell magnet *m*, and the bell B, which in practice would be vibratory, rings. The wheel *w* can be adjusted on its shaft *s*, so as to be in a different position at each station.

There are of course many other ways of utilizing these principles, one being shown in Fig. 2, which is one of the drawings of a patent taken out by Messrs. Curtis and Crocker.

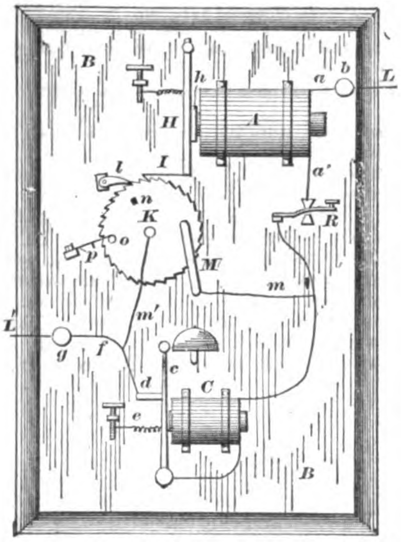

Fig. 2.

This general plan No. 4 has been much favored by inventors, admits of almost indefinite variation, and is easily associated with auxiliary devices such as unisons, busy signals, and lockouts for apparatus at other stations. If mechanism properly designed and made, be employed, there is no reason why satisfactory results might not be expected. Cheap apparatus has however invariably been tried and the system besides is slow. [No. 212,792, March 4, 1879, E. N. Dickerson, Jr. No. 230,530, July 27, 1880, Curtis and Crocker.]

5. *Clockwork Bells.*

a. Those in which a constantly running clock-train brings the bells at the different stations into circuit successively, or removes a mechanical holder from their hammers; when only they can be rung. These are not reliable; it being impossible to keep the clocks together; the clocks also require too frequent winding. [Patent 223,469, January 13, 1880, Bliss.]

b. Those in which at each station is a normally stopped clock-train. All clocks are started by the same initial pulsation, and bring their signals to ringing points, or their bells into circuit at different times.

This idea is one of the most practical that has been advanced, and if the apparatus is well designed, and put together in a good mechanical form, it ought to do good work; unfortunately, first-class apparatus is costly enough to remove the gilt from the economical side of the selective signal.

This plan is indicated by the diagram Fig. 3, in which, however, the clockwork is not shown. In the diagram H is supposed to be the signal transmitting, and S the signal receiving station, at each of which is a metal circuit wheel B, by which in conjunction with the circuit springs *s* and *v*, the bells *b* are, when at rest, short-circuited. At the transmitting station is a circuit-closing key K, a battery V having one pole united to earth or return G, and the other extended to the front contact V' of the key, and a duplicate W, of the several sub-station instruments.

The first pressure of the key through suitable mechanism starts the clock-works at all stations, and introduces the bells at each station successively, as the wheels B bring their notches under the springs *v*. The wheels are in the present instant supposed to be slow moving, and to have six ringing notches for each complete revolution. They can by suitable mechanism be stopped on each notch to ring a given bell as long as may be desired; and they come to rest after one notch at all stations has passed under its spring.

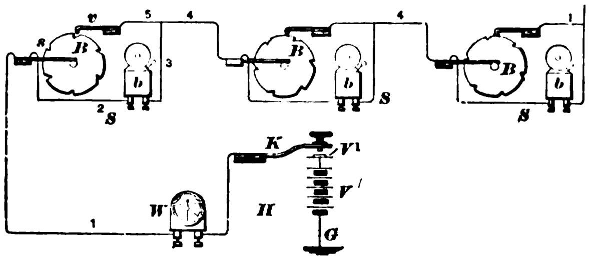

Fig. 3.

Of course the notches are arranged to pass under the springs at different times for the several stations, and this is indicated in the figure, where the bell at the nearest station is introduced into the circuit; the springs *v* of the others being at different positions on the periphery of the wheel. [Patent 232,442, Sept. 21, 1880, Blake.]

c. Those in which a normally quiescent clock-train is controlled by an electromagnetic escapement, and permitted to move by successive beats, as a key at the central station alternately makes and breaks the circuit. [Patent 228,047, May 25, 1880, Eaton.]

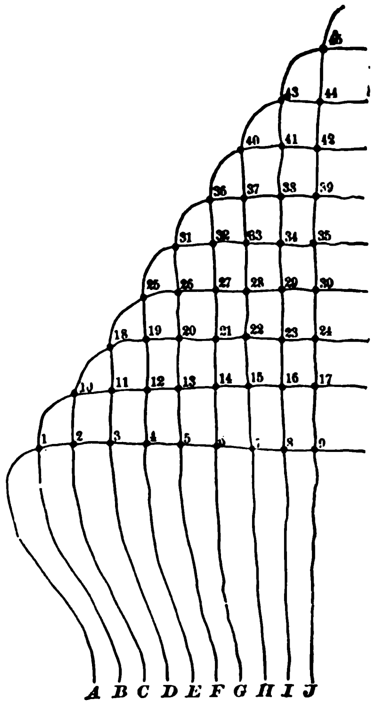

Fig. 4.

This could doubtless be made to work all right by putting excellent apparatus into it, but like nearly all step-by-step devices, would generally be slow.[10]

---

[10] All of the subdivisions of class 5, may either have the signaling device directly in the main circuit, or in a local circuit to be closed by the action of the main circuit.

6. *Bells in which all the hammers move forward to strike at the same time, but except the desired one are prevented from striking by an interposed mechanical obstacle, which in the bell of the wanted station is removed.*

This has been faithfully tried. It was operated by an electro-magnetic ratchet and pawl, and was uncertain in operation. It also developed another fault, viz., that even the bells which are not to respond, make a considerable rattling. [Patent No. 219,059, Sept. 2, 1879, Anders.]

7. *Bells in which the ringing is done by circuit arrangement, or conductor combinations. Two series of circuits may radiate from a central to a number of sub-stations, and one of each series caused to enter all stations. No two stations, however, have the same two circuits. Only when the current traverses both circuits does the bell ring at the station they enter.*

This is very promising. It cannot, however, be applied to a multiple switchboard system, It requires relays and a local circuit bell ; but no specially constructed apparatus. It is also very speedy; the single pressure of a given key will always ring a given bell, and no mistake can be made. This system is roughly illustrated by the diagram, Fig. 4, in which each outgoing conductor is shown to intersect each other conductor at some one sub-station, and thus afford facilities for producing a selective signal for 45 stations by using but 10 main lines.

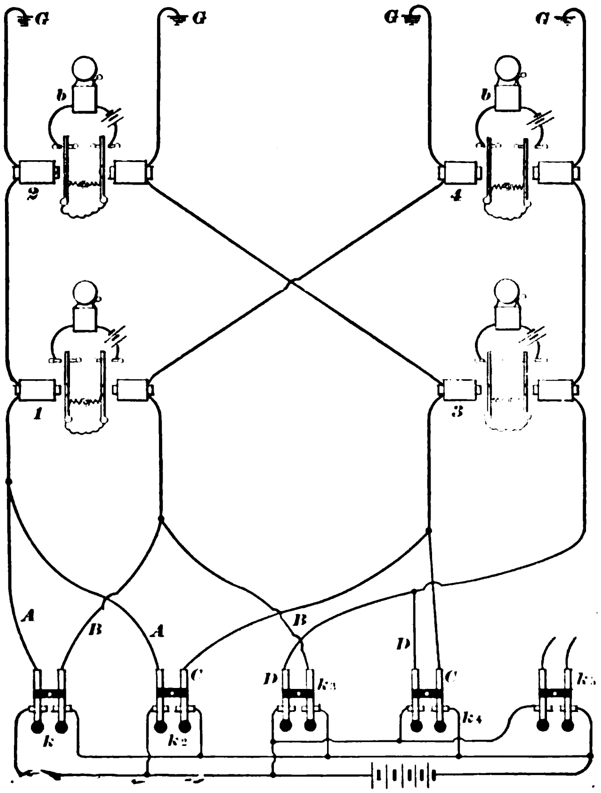

Fig. 5.

For example, if it be desired to signal station 41, it will be necessary to manipulate the lines G and I.

The diagram Fig. 5, more fully illustrates one way in which the idea is worked out, although there are several plans, all of which are more or less advantageous. A battery, B, branches its two poles to each of a series of keys *k*, each of which controls the terminals of two lines; for example, key *k* may control terminals of A and B, k^2 those of A and C, and so on.

At each sub-station two lines both enter and pass respectively through relays, and the concurrent action of the two relays at any station is required to ring the bell, since the bell circuit is led through the armature levers and their front contacts of both.

Taking the conductors in pairs, the number of possible combinations is represented by the expression $\frac{n^2-n}{2}$ and that number of separate stations can be selectively signaled by the use of *n* wires. [Patent No. 219,188, Sept, 2, 1879, Vail; Patent No. 224,855, Feb'y 24, 1880, Vail.]

8. *Bells working on the principles of harmonic telegraphy.* At each station the spring, pendulum or reed carrying the bell hammer is tuned to respond to a different note or rate of vibration.

The central station transmitting device is adjustable, and can have its rate made to correspond with that of any sub-station bell. When set in operation the coinciding bell only will ring. Operated always by experts, and carefully constructed and adjusted, these might do well. They are, however, too sensitive; tend to become operative as their proper number of vibrations is approached, and in some degree become irregular with temperature changes. Fig. 6 illustrates the idea, and shows a central and three sub-stations.

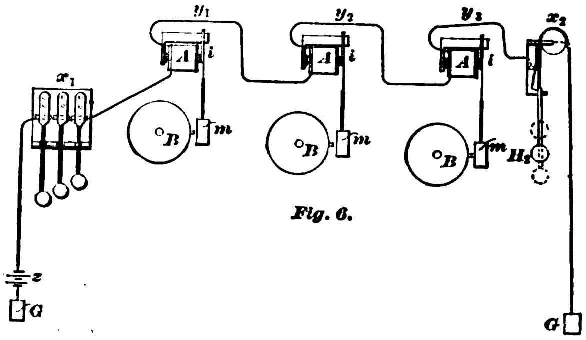

Fig. 6.

9. *Sub-station signals in which galvanometers, identically constructed and calibrated, make the same deflection with a given current; to ring the bells different currents are sent, which produce different deflections. Each, of course, has its ringing deflection at a different point, which may by a mercury cup close a local circuit.*

These signals ought to work fairly well, if sufficient care and cost be put into them. It would not be difficult to add several other classes to this list, but those which have been mentioned are the most important. [Patent No. 262,252, Aug. 8, 1882, Southworth.]

The plans of greatest promise are:

A. Those which by clockwork (as in 5*b*) are brought to a ringing point differing for each, the clockwork being then stopped, and the ringing done by a different kind of current. This is virtually the same plan of operation as is employed in the stock quotation printing telegraphs, and is reliable, but, when adapted to do the work well, costly.

B. Those which as in class 7, require the coaction of two circuits.

Either of these when adopted should be worked in connection with a local battery.

Probably in practice it will be found advantageous to have a separate circuit distinct from the telephone circuit, on which a great number of selective signals may be connected.

The unison or zero device in some form may be considered as an essential auxiliary in all progressive signals, whether of the clockwork or step-by-step orders. Even the most perfect mechanism slips occasionally, and as in the stock printing systems where instruments "throw out" or get out of step with each other, a suitable zero at which all can periodically be brought to rest, and start even, must be certainly required. A "busy" signal which indicates at each station whether the line is in use at any other is useful, but not essential. And lock-out apparatus, usually provided by closing a shunt circuit round the call-sending mechanism and telephones, at all stations on a circuit, except the

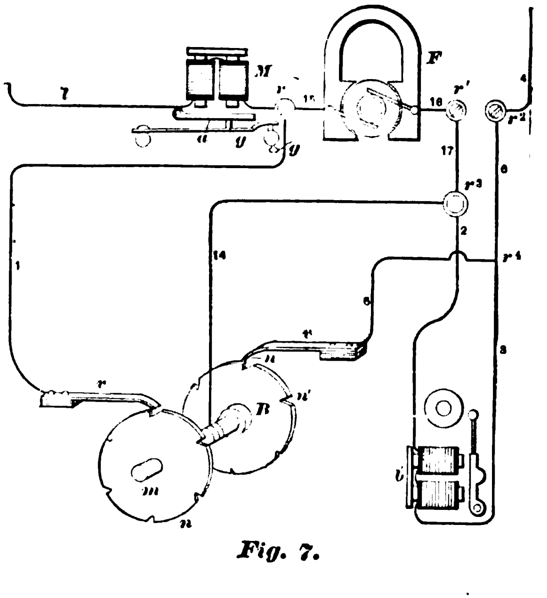

Fig. 7.

one or two which are actually communicating, is also highly advisable in order that privacy and freedom from interruption may be maintained.

But, while some of these devices are necessary, and all useful if reliable, the contriver from this time forward must keep at all times before his eyes, the undoubted fact that selective signals where heretofore tried, have uniformly been handicapped by being too intimately associated with too many such auxiliary devices, and must be correspondingly cautious about the way in which they are added.

Some such mode as is depicted in Fig. 7 is best for this purpose.

In the figure, M is a clock-tripping magnet; F the magneto generator for sending outgoing calls, *b* the station bell, and *m* and *n* two metallic wheel commutators mounted on, and electrically connected with the same shaft B. Arranged to press on the periphery of *m* is a contact spring *v′* and similarly placed with respect to *n*, is a spring *v*.

When the station mechanism is at rest, it is desirable to have the generators in the line circuit, but the bells out. Accordingly, the bell is short-circuited through the disk *n*, spring *v*, and wires 14 and 5; while a possible shunt circuit round the generator through disk *m*, spring *v′*, and wires 1 and 14 is open, the spring *v′* being over the notch. The notches of *m* are placed alike at all stations, but those of *n* differ at all stations; and therefore as soon as the shaft *B* begins to move, when the driving clock-train is tripped, the shunt circuit is established round all the station generators, and no station can interrupt by an attempt to send a call signal.

Such a device is well enough because it can generally be added without at all impeding the operation of the signal proper, and in any case constitutes a perfectly proper adjunct to the equipment of a party line. But when associated with selective signals the greatest care is necessary to provide that the arrangement is such that the auxiliary appliance may not prove a drag on the signaling mechanism.

Selective signals require a fair field and all the favor they can get.

RAILWAY TRAIN LIGHTING.[1]

BY A. H. BAUER.

THE first successful system of railway train lighting is that invented by Houghton, and adopted by the London, Brighton and South Coast Railway of England, in 1881–2. Since then the many improvements suggested by other inventors have made it almost automatic.

The system consists of a Brush dynamo carried inside the baggage compartment, and directly connected by link belting to pulleys on the axle of the car. Attached to the dynamo is a ball governor, rotating vertically, whose office is as follows:

1st. To control the movement of a switch, which, when the speed and therefore the E. M. F. of the dynamo reaches a predetermined value closes the circuit, and also opens it again when the E. M. F. approximates that of the secondary battery.

2d. The adjustment of a resistance which maintains the current constant, and

3d. To shift the position of the brushes as the neutral point is changed by the varying speed of the armature.

But one set of brushes is used, carried in rectangular holders, at right angles to the commutator, and always in contact with it.

When the rotation of the armature is reversed by a change of direction of the train, the brushes are carried forward or backward by the friction on the commutator and a connection with the governor until the quadrant passes but a fraction beyond the vertical, when it is drawn to the proper position by a spring, the action being similar to that of the snap switch. Limiting stops are provided to prevent the quadrant going too far.

The same movement of the quadrant also changes the position of a switch controlling the connection of the field coils, and therefore the polarity of the dynamo. It therefore follows that the current is always in the same direction, no matter in which direction the armature may rotate. One set of accumulators, consisting of 25 cells, is provided for each train, and placed in the baggage compartment. The maximum number of lamps in a train is 70, of 10 c. p. each, at 50 volts. No attendant is necessary, but at certain stations on the line an examination of the plant is made, and required repairs attended to. I am informed the system is so reliable that since the year 1888 but two failures have occurred.

It will be noted that the key of this system is the convenience with which the connection between the armature pulley and that on the axle can be made. Throughout Europe the rigid wheel base is universally employed under railway cars; consequently, by setting the dynamo across the car, the armature shaft will always be parallel with the axle, and the connecting belt runs in practically the same plane.

In this country the bogie truck is exclusively used. Several attempts have been made to drive dynamos by connections with the axle of bogie trucks. All, however, have failed, for the reason that no provision was made for maintaining the armature shaft and axle parallel at all angles of the truck, and because sand, dirt, etc., gathered by a moving truck will soon destroy any mechanism that may be used for the purpose under the car. The problem, however, has not been abandoned, and I am in hopes that within a very short time a solution will be found.

Numerous propositions have been made to use primary batteries for car lighting, but I am not informed of a successful installation of that character.

Secondary or storage batteries have been more or less employed for the purpose, with varying success. The first attempt in this direction was made in 1887–8 on two Pullman limited trains of six cars each. Each car was equipped with 30 cells of battery, having a capacity of 150 ampere hours, and weighing 50 pounds per cell, or 1,500 pounds per car. Duplicate sets were kept charged at each end of the line, and, on arrival of the train, exchanged for those that had been exhausted while on the road. The average number of lamps per car was 26, of 16 c. p., at 60 volts, or a total of 156 in the train. After 60 days' trial, it was clearly demonstrated that, under existing conditions, the system could not be made successful, and it was abandoned.

The reasons for its failure were that the capacity of the battery was insufficient to maintain the number of lamps required for the proper lighting of Pullman cars on long runs.

A second reason was the deterioration of the batteries themselves, which were of the pasted grid type. Close observation indicated the loss during one handling to be equal to, if not more, than that caused by 1,000 miles of travel on the car. This was five years ago. Since then, improved methods of manufacture, as well as more intelligent care in handling, has, to a great extent, overcome their objections and thereby increased the life of the battery.

Since these experiments were made, car lighting for short distance, only, from storage batteries, has been made successful. For the past two years four cars, each equipped with 32 cells of 150 ampere hours capacity and 26 16-c. p. 60-volt lamps have been running between Chicago and Cincinnati, and Chicago and Indianapolis. Two of these cars are charged every day at Chicago for about nine hours with sufficient current for a round trip. The batteries, however, are not changed; the cars are always placed on the same side track to which wires from the dynamo are led, and the charging is done without removing them. The average length of time the light is required during a round trip is six hours; the cars leave each end of the line at 8 and 9 p. m. respectively. Repairs are made by removing the defective cell and substituting another if necessary.

The cost of repairs and renewals of all kinds from September, 1891, to January, 1892, inclusive, per month, was as follows:

September, 1891	$36.44
October, "	108.82
November, "	51.24
December, "	79.21
January, 1892	38.31
Total	$314.02

which, divided by four, is $78.50 per car per month, or $2.61 per car per day, and this divided by 26 gives 10 cents as the cost per lamp per day. As the engine and boiler are used for furnishing power for other purposes while running the charging dynamo, it is difficult to get the cost of the power for charging these batteries, that factor, therefore, is not included in the above statement.

In January, 1888, a solution of the problem of lighting six-car trains for long distances was sought for in another direction. Two trains running between Jersey City and Jacksonville, Florida, a distance of 1,100 miles, were selected for the experiment. At first an attempt was made to utilize the power of the axle, but for reasons already stated did not prove successful.

The next step was the substitution of a vertical single-stroke engine, located in the baggage car, for the axle connection.

The system which has been used for the past five years on all Pullman trains, consists of a Brotherhood three-cylinder engine and Eickemeyer dynamo, bolted to a cast-iron bed-plate, and located in the forward end of the baggage car, occupying an enclosed space of 6 feet 6 inches by 3 feet 3 inches. The engine and dynamo are connected by a flexible coupling which allows for the irregularity should they not be in perfect line. A two-gallon sight-feed pressure lubricator bolted to the end of the car, furnishes oil to all wearing parts of the engine. The average consumption of oil is about one gallon every 20 hours of actual running of the engine.

Steam is taken from the locomotive boiler, a tap being made at the dome, the pipe passing under the tender and car, between which a flexible rubber hose makes connection. With 50 pounds pressure, the dynamo will, at 900 revolutions, generate 80 amperes, at 72 volts, when all the lamps and batteries in a six-car train are in circuit; and 50 to 75 amperes, at 80 to 85 volts, at the same speed when the batteries alone are connected, depending on the counter E. M. F. of the batteries.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, Ill., June 6, 7 and 8, 1892.

On the side of the car is placed an automatic switch, which will break the circuit when the E. M. F. of the dynamo equals that of the batteries. A voltmeter and ammeter are kept constantly in circuit while the plant is in operation. A tachometer, belted to the armature shaft, is also provided for noting the speed of the engine and dynamo. This plant is enclosed by a tongue-and-groove partition surmounted by a wire screen.

The system of wiring adopted is the equi-potential, in which the pressure is practically equal at each lamp and battery. A third wire leads from the negative pole of the dynamo to the rear end of the rear car, where it ends. This third wire is tapped to the negative pole of each battery and the remaining side of each lamp. The wires are always placed on the roof of a car. For this purpose whitewood mouldings, thickly coated with asphalt paint, is nailed from end to end as near the centre as possible, usually $1\frac{3}{4}$ inch from the edge of the smoke-jack if the car is equipped with centre oil lamps, and from 6 to 24 inches when gas lamps are applied.

The sizes of wire used are all of B. & S. gauge, and consist of No. 2 for those leading from the dynamo, Nos. 6 and 10 for the lamp mains and No. 14 for the lamp drops. The connection between cars is made by bringing the wires from the roof through the hood to the inside of the vestibule, where they terminate in square brass tubing called connectors, which are permanently attached to the vestibule frame. The connection between these connectors is made with three-conductor flexible cables, each conductor of No. 6 gauge.

When the batteries alone are in circuit, the E. M. F. of the dynamo will be from 67 to 83 volts, which, minus the loss, will overcome the counter E. M. F. of the batteries, viz., 57.6 to 73.6 volts. When both lamps and batteries are in circuit the external resistance is of course reduced and the E. M. F. of the dynamo falls in proportion, and that at the lamps will be from 60 to 66 volts.

Each car is provided with 32 cells of storage batteries, placed 16 in each of two boxes, securely fastened under the centre, and directly over the truss rod. The weight of batteries and boxes complete, is about 2,000 pounds. As already stated, with the system of wiring adopted the batteries and lamps are permanently connected in multiple arc, so that should the train be parted and connection with the dynamo become broken the batteries will supply current necessary to maintain the light; or should the batteries under one car become disconnected, its lamps will be supplied from batteries under other cars in the train.

The lamp equipment of a six-car Pullman train is as follows:

Combined smoking and baggage car	21 lamps.
Dining car	32 "
Three sleeping cars	90 "
Combined observation and sleeping car	29 "
Total	172 lamps.

Of this number, 98 are 16 c. p. and 74 are 8 c. p. The latter are placed in hallways, toilet-rooms and vestibules. During six months of the year, seven $\frac{1}{8}$ h. p. fan motors are added, viz., three in the dining, two in the smoking and two in the observation cars, each absorbing the current of four 16 c. p. lamps, or a total of 28, which, added to the 172, makes the total, 200 lamps in the train. To maintain the 200 lamps requires 144 amperes. As the dynamo will generate but 80, the batteries must supply 64 amperes, or 44 per cent. This is effected by charging the batteries during the day and part of the night *en route*, and while the train is standing in the yards.

The following, taken from the January records of a train, will give an idea of the number of lamp hours required:

CHICAGO TO JERSEY CITY.

Time.	Hours.	No. of lamps.	Lamp hours.	
4 A. M. to 9 P. M.	5	172	860	Leaving Chicago.
9 " 11 "	2	140	280	
11 " 12 "	1	42	42	
4 " 7 "	3	172	516	Arriving at Jersey City.
During day in tunnels and depots	1	172	172	
Total			1,870	

JERSEY CITY TO CHICAGO.

Time.	Hours.	No. of lamps.	Lamp hours.	
4 P. M. to 9:30 P. M.	5½	172	946	Leaving Jersey City.
9:30 " 11 "	1½	140	210	
11 " 12 "	1	42	42	
6 A. M. to 7:30 A. M.	1½	32	48	Arriving at Chicago.
During day in tunnels and depots	1	172	172	
Total			1,418	

Total, 3,288 lamp hours during the round trip.

The cost of an installation for a six-car Pullman train—consisting of one combined baggage and smoking, three sleeping, one dining and one combined sleeping and observation car is $5,808.20, or an average of $968.00 per car. As the fan motors are used but six months in the year, the average number of lamps will be 172 + 14 = 186. Therefore, the cost of equipment per lamp will be $5,808.26 ÷ 186 = $31.22.

The average cost of labor and material for maintaining the lighting of three trains, or 18 cars for 19 months, from August, 1890, to February, 1892, inclusive, was as follows:

Average total cost per month			$1,265.95
"	"	per car per day	1.99
"	"	of labor per month	712.39
"	"	" per car per day	1.11
"	"	of material per month	511.51
"	"	" per car per day	87
"	"	per lamp per day	07.17
Average number of lamps in use			558

The item of labor includes the wages of five attendants on the train, at $3.00 per day each, and two men at each terminal station, at $90.00 and $55.00, and $75.00 and $50.00 per month respectively. That of material includes the cost of renewal of batteries, etc.

The cost of labor is practically constant, while that of material varies from 12 cents to $2.04 per car per day, the average for 19 months being 87 cents. The cost per lamp per day varies from $3\frac{8}{10}$ cents to $12\frac{5}{10}$ cents; the average is 7.17 cents.

The cost of power furnished by the locomotive boiler is not included in the statement, for the reason that a satisfactory measurement of the quantity of coal and water used has never been made.

So long as the dynamo can be run, and the batteries properly charged, the system is reliable.

During the coldest part of the winter, or as sometimes happens, when a poor quality of coal is furnished, it is difficult for the locomotive to supply sufficient steam to run the dynamo. In such cases the batteries are called upon to maintain the light. As a rule, they have sufficient charge to do so for about four hours. Trains so equipped have been run between Jersey City and St. Augustine, Florida, during the months of January, February, March and April of each year since 1888. The system has also been used on other trains, viz., between New Orleans and the City of Mexico, Omaha and San Francisco, Chicago and Portland, Me.

It was early seen that the only uncertainty connected with the system is due to the absolute dependence upon the locomotive boiler for power to run the dynamo, for, as explained, there is a constant liability of the failure of the steam supply which, if prolonged beyond the capacity of the battery will result in the use of oil or gas for light. As many other problems connected with the system have been successfully worked out, it is believed that the solution of this one will also be found.

There is no doubt that the ideal way of running the dynamo is by a connection with the axle. Many apparent solutions have been suggested, only to be condemned as uncertain or impracticable. It is, however, thought that within the next year a reliable connection will be had, after which I believe the lighting of railway trains by electricity will be universally adopted.

SOME POINTS FOR THE ELECTRICAL ENGINEER.[1]

BY HORATIO A. FOSTER.

It has been the fortune of the writer during the last 10 months to visit and inspect, both technically and financially, considerably more than a hundred central lighting stations. Taken as a whole, it really seems as if much of the ordinary commercial common sense and the usual keen judgment of self-interest had been on a vacation when these plants were erected.

So much diversity of opinion is shown in designing these stations, and oftentimes by those whose opinion should have no weight, but unfortunately does, that it has the effect to convince some of the investing public that the electrical engineer does not know his business and they might as well go it alone. If some action could be taken by this Institute through a committee which should examine into proper station design and report on some few general plans and suggestions as to lines to be followed, it might go far toward establishing a better backing for our members who are in that branch.

Quite often officials of the electric lighting companies take a jaunt through the country visiting different stations for models for a new one for themselves. This often results in a worse muddle than ever, as they seldom find two stations at all similar, and they return resolved to use their own judgment. This leaves the real electrical engineer out in the cold, at a point where, if known, he could by consultation do much good; but many of these company officials never heard of the American Institute of Electrical Engineers and need to have it brought to their notice in some way. Perhaps if instances be mentioned under the folwing heads a better understanding can be arrived at, viz.: cation ; foundations ; construction of station ; motive power ; rangement of machinery, and location and construction of lines.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, Ill., June 6, 7 and 8, 1892.

Location.—The location of plants is not now so generally bad as in the past, although we occasionally find a station in a location for which no excuse is apparent, as, for instance, one located in the basement of a carpenter shop at a long distance from fuel supplies, and only plenty of condensing water to recommend it ; insurance rate, three per cent. or more. Another located nine miles away from a village of 2,000 people to take advantage of water-power never surely available all the year, and since destroyed entirely for the greater part of the year.

One advantage of some of the older centrally located stations has since been learned in the increase in value of such real estate. One such station visited will enlarge and rebuild soon, and will sell its present real estate for enough advance to go far toward paying for the new station, and there are others which can, I think, tell the same story. In fact, in the present problematical growth of the future, a well-selected piece of ground may prove a very valuable part of the investment.

Foundations.—Foundations are now much better than in the past, and some of those now placed under dynamos would sustain almost anything that could be put on them. Poor foundations are occasionally seen though, as for instance those under a large bank of boilers in a station which was erected and started in six weeks. The boilers have since lurched forward until the fronts are some two or three inches out of plumb. In fact too little attention seems to have been paid to boiler foundations as a general thing. Engines have fared better and when the ground has been good the foundations are to be little criticised.

Very few bad dynamo foundations are now met, but many unbalanced armatures are found which no amount of foundation would hold steady.

Station Construction.—In station construction there has been no settled design, therefore the promoters have generally built as they saw fit, occasionally following suggestions of the agent. Of course many plants are located in buildings already up, in which case the machinery had to be made to fit.

In many of those built especially for the work, no attention has been paid to designing for a low insurance rate, and brick stations are found sheathed all over the inside with pine, the one thing that insurance inspectors always criticise. A couple of coatings of whitewash or paint would have been much cheaper, safer, and looked quite as well.

When stations have been remodeled, very little improvement has been made in the smaller ones, but those in large cities have generally taken advantage of all the improvements to date, if not too strongly attached to some one parent company.

Motive Power.—The selection of motive power has of course been governed by local conditions; in the northern and northwestern part of New York State, water-power is abundant and is largely used as motive power for stations, but almost invariably with steam reserve. Water-power alone has been found very difficult to govern for uniform speed, and some of the devices used for that purpose are, to say the least, ingenious.

Of engines there is no end to the different design, style and size used. Some use high speed, belted direct to dynamos, others slow speed belted to counter, some simple non-condensing where compound condensing would be decidedly best. I know of at least three plants located in water-works pumping stations, using high speed simple non-condensing engines on a practically steady load, all of which have been erected during the past three or four years.

Two stations I remember having an all-night and every-night load of arc lights and situated on a lake shore which run high speed simple non-condensing engines.

To offset this there is one station that deserves mention as it embodies many points of value. The building is substantial, of brick, two stories high and on a river bank. The boilers are very efficient and well set, the engine is a moderate speed compound condensing, with shaft extended for three dynamo pulleys, and one for the power condenser. There is a heater between the exhaust and condenser and a power pump attached to one side of the condenser. The flow to the boilers is governed by a bye-pass valve, as the pump is of course in motion all the time the engine is running. This station has only an arc load and runs all night; it was built entirely under the supervision of a local mechanical engineer with the exception of connecting the lines and dynamo terminals to the switchboard, and would, I think, be hard to beat for results.

Arrangement of Machinery.—The arrangement of machinery is as diverse as the style of motive power; when direct belting is used the arrangement is generally simple and plain, but oftentimes so crowded as to be very inconvenient.

There seems no end to the arrangement of shafting; some have a line shaft through the middle of the dynamo-room and belt both ways to dynamos, others a shaft on either side of the room belting to dynamos in the centre, others the shaft under the floor belting up to dynamos and occasionally to engines also, others have the shafting overhead; in fact, there is no end to the styles, some good and some bad. In most cases friction clutches are used with shafting for stopping individual dynamos and some few may use loose pulleys on independent sleeve for the same purpose.

The length of belt centres varies greatly, some apparently thinking if long belts are better than short, very long ones must be much the best.

The improvement in switchboards seems to me more marked than in any other one department, which is probably owing to the pressure of insurance men who look at the switchboard as the most dangerous fire risk of all.

Line Construction.—In line construction I cannot see that any very marked improvement has been made, excepting in some cases, the substitution of larger and better poles for the older ones. The use of black-covered wire in place of white has perhaps made the lines a trifle less conspicuous but that is about all. The lines still have the apparent aimlessness of direction mentioned by Prof. Thomson at Buffalo. People in the larger interior cities are already agitating the question of underground wires and it seems probable that unless something is done soon by the companies themselves to rid the streets of the more conspicuous of these wires, there will be very costly trouble for them to contend with.

In street lighting the favorite method is the cable suspension across the street. Where the work is neatly done this serves very well but it would be difficult to find a more unsightly thing than some of the lamps so suspended. Considerable trouble is occasioned in the above method by breakage of the wires at the joint with the line and at the cross-bar over the hood. There is no apparent reason why twin or duplex wire should not be more used for this purpose, instead of the kinked and straggly single wires.

It seems to me that if some action was taken by a non-partisan association like this Institute, an advance toward better engineering might be made, if a few general laws could be suggested to be followed in laying out the different parts of a lighting station. Perhaps it may be said that much of the above work should more properly come before the National Electric Light Association, but as many of that society are members of this Institute, I feel sure they would individually appreciate its backing in the future when the time comes for enlargement, and they have need of combined expert opinion.

Society and Club Notes.

PROF. E. J. HOUSTON BEFORE THE BROOKLYN INSTITUTE.

A MOST interesting, instructive and suggestive lecture was delivered on Wednesday, June 1, before the Electrical Section of the Brooklyn Institute, by Prof. E. J. Houston, on "The Advance of Electricity During the Last Hundred Years." In addition to reviewing the work done in various departments of electrical science and application, Prof. Houston touched on many points of importance concerning all branches of invention and discovery. Great ideas or inventions can be arranged he said, under three great types or classes, viz : 1. Immature or incomplete ; 2. Mature but unripe ; 3. Ripe. Ideas or inventions of the first type produce but little effect in the world—at times, however, they tend to direct thought to certain channels and thus act as forerunners of greater and more valuable ideas. Ideas of the second type are mature, but the times are unripe for them ; the condition of the environment is unsuited, and therefore, though matured and complete in themselves, like unripe fruit they produce no progeny for the development of the world.

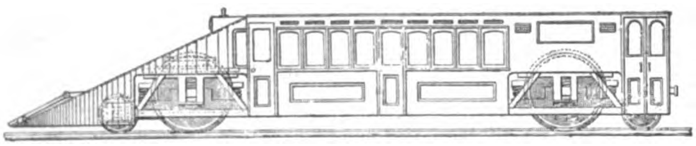
Ideas or inventions of the third type are of far greater value to the world than those of the second type, since they bear fruit almost immediately. It matters little to the world whether they have been conceived before or not. When practicable, they must necessarily find birth or creation as soon as the times are ripe for them. The fact that such ideas are subsequently found to be old ones does not prevent them from being original with their later producer. As to this class of inventions, if the world is ripe and ready to receive them, it may happen that they may be made in different parts of the world at about the same time. Prof. Youmans expresses it as his opinion that great ideas belong to eras rather than to individuals ; that intellectual progress may move in waves toward the boundaries of the unknown, and many investigators moving with that wave may, at very nearly the same time, discover new features and facts on the horizon beyond.

Prof. Houston went on to show how most if not all of the great electrical industries had passed through these stages, and how one invention sprang from another. He predicted that as the result of what had already been seen and done, the near future would enjoy a cheaper means of producing electricity than the present dynamo-electric machine ; the entire replacement of the steam engine by the electric motor ; the solution of the problem of aerial navigation by means of electricity ; the substitution of the present electric light by other forms of the kind exhibited by Nikola Tesla, and a more intelligent therapeutical application of the electric current.

"FROM CHICAGO TO ST. LOUIS BY ELECTRIC EXPRESS."

UNDER the above title a very striking address was delivered at the New York Electric Club, on Thursday evening, June 2d, by Dr. Wellington Adams, of St. Louis, with the help of a number of lantern slides illustrative of the line of road and the apparatus which it is proposed to use. The road is to be 248 miles long and will be absolutely straight except where it curves into the cities of St. Louis and Chicago. For at least 200 miles the country is as level as a billiard table, and the worst grade on the whole line does not exceed two per cent. There will be two main tracks, and later other parallel tracks are to be built for trains that are not through expresses. The road-bed will be drained, will have a ditch on each side, and will be laid with 70-pound overlapping rail, so making a continuous circuit. Between the two road-beds or tracks will be centre poles carrying the trolley wires to supply the current, and the line will be divided up into ten-mile sections, so that the service wire on each will deliver an alternating current of 100 amperes at 3,000 volts. Current is to be fed into the primary line from two generating stations and raised to 25,000 volts and then lowered to 3,000 by a converter for each section. There are to be two generating stations along the line, one about 60 miles from Chicago utilizing a water-fall of 10,000 h. p. and the other at a coal mine at Edinburg, about the same distance from St. Louis These are each, therefore, equidistant from the terminals and will take care of an equal part of the line on each side of them.

The service of transportation will be done by means of individual motor cars of the type shown in the accompanying engraving. Each car will weigh about 15 tons. The roof will be only nine feet above the rails. The driving wheels will be six feet in diameter, and on the bogie truck at each end of the car, driving directly, will be a 200 h. p. alternating current motor, apparently of the synchronous type. Each motor will weigh 6,130 pounds and give 200 h. p at 500 revolutions per minute. Forty passengers and mail and express matter can be carried. There will be a pilot wheel in front and one at the rear. The forward end of the car is cone-shaped to lessen the atmospheric resistance. The one driver and attendant stands in the front compartment. He is to do everything including the collection of tickets. The trolley arrangement is to consist of two sliding shoe contacts, between which is a 12-inch wheel maintaining touch with the line. The trolley wire will be but slightly above the roof of the car and is to be so carried by poles and suspensions as not to sag.



ADAMS HIGH-SPEED MOTOR CAR.

The cost of the road is placed at $6,000,000. Over 60 per cent. of the right of way has already been secured. The company counts on getting its road ready in time for the World's Fair and on carrying there 3,000,000 passengers at $5 each for the round trip. At present there are 1,200 through passengers between Chicago and St. Louis daily, and the carriage of the mails pays $105,000 per annum. The proposed running time will be 2½ hours as compared with 8½ as at present.

After the lecture, Mr. G. M. Phelps, who presided, asked for a discussion of the daring project thus unfolded. Mr. O. T. Crosby and Prof. George Forbes were both of a rather doubtful and misgiving state of mind, and while they wished Dr. Adams success, they seemed to question the practicability of his schemes. Dr. Adams said in conclusion that he could not, for reasons as to patents, etc., go into further details of his proposed apparatus.

CHICAGO ELECTRICAL ASSOCIATION.

THE meeting on June 14th will be held at Atheneum Hall, 28 Van Buren street, where Mr. George Cutter will have facilities for an illustrated lecture on "Thomson's Induction Experiments." The principles underlying the modern applications of the alternating current are now widely known, yet comparatively few have seen the interesting experiments devised by Prof. Elihu Thomson. Mr. Cutter has built apparatus for repeating many of these, and will also show a number of new experiments bearing on the same lines. All interested will be welcomed by the association.

THE COMMISSIONERS OF THE DISTRICT OF COLUMBIA recently gave notice that all the theatres of Washington must be fitted throughout with electric lights.

Literature.

American Telegraphy: Systems, Apparatus, Operation. By William Maver, Jr., Electrician Consolidated Telegraph and Electrical Subway Company; Ex-Electrician Baltimore and Ohio Telegraph Company, etc. With 450 illustrations. *New York*, 1892. J. H. Bunnell & Co. Large 8vo, pp. xvi + 574. Price $5.00.

ALTHOUGH MR. MAVER has chosen a comprehensive title for his work, it may be truthfully said that his treatment of the subject has been no less comprehensive than the title indicates. In his introductory chapter the author tells us that in its modern signification, the word "telegraph" embraces "any means whereby intelligence is conveyed to a distance by signs or sounds," and it is from this generic standpoint that he has chosen to deal with the subject of American telegraphy. Of the vast expenditure of labor and time required to accomplish such a result in an adequate manner, no person unfamiliar with the field of applied electricity as it exists to-day can form the slightest conception. Whether it was worth while to undertake to embody the results of such a wide research within the limits of a single volume is a question which it is perhaps unnecessary for us to discuss; but it can scarcely be gainsaid that not only the electrical industries in general, but even that department of them relating exclusively to telegraphy, using the word in its broadest sense, have become so largely specialized by the rapid and diverse progress of invention and application, that it is no longer possible for any one person to hope to become an adept in every branch of the art. Accordingly, we see in later years a marked tendency towards the production of books in which the author has confined himself to an attempt to treat exhaustively some special branch of the art; books of which Kempe's "Handbook of Testing" and Douglas's "Telegraphic Construction" may be mentioned as examples. But standing as we do to day, in a certain sense, at the parting of the ways between the old and the new, it is at all events not to be regretted that one so exceptionally well qualified for the task as Mr. Maver should have undertaken a minute and detailed survey of the entire field, so that all who come after may be enabled to know, in the language of the technical expert, the precise "state of the art" as it existed in A. D. 1892.

Of the 574 large pages of text of Mr. Maver's work, approximately one-half is devoted to a description of the standard Morse telegraphic apparatus in its various modern commercial applications, together with the innumerable details having to do with its installation and practical management. In the remaining portion of the work, the author has managed to find room to discuss almost every form of apparatus known or used in the United States for the communication of intelligence to a distance by means of electricity. In telegraphy proper for example, we find the submarine, automatic, autographic, typographic, and synchronous multiplex. Then we have the numerous special systems for communicating alarms and signals, such as the time-service, the district messenger call, the fire-alarm, the municipal or police service, the railway block systems, the burglar alarm, and so on. There are also special chapters devoted to subterranean and subaqueous lines and cables; and the construction and maintenance of land lines, together with examples of specifications of apparatus and material, and a variety of useful tables of the weight and dimensions of commercial wires, and other cognate matter.

It must by no means be inferred, from what has been said as to the extended scope of Mr. Maver's work, that the several systems and apparatus referred to have failed to receive adequate individual treatment at his hands. On the contrary, if any error has been committed, we should be inclined to say that it is rather in the opposite direction, that of over-elaboration. The author's strong point evidently lies in his thorough mastery of the minutiæ of the every-day working of electrical apparatus, and his unusual capacity for taking infinite pains in the conscientious explanation of what each instrument does, how it does it and why it does it. This predilection for detail, combined with a certain distaste or lack of capacity for generalization which is apparently inherent in the mental constitution of the author, gives to the work an encyclopædic character, which, while not in the least detracting from its merits as a book of reference, nevertheless may possibly tend to render it somewhat tedious to the general scientific reader.

Keeping in mind these limitations, which, after all, have reference only to the general plan and scope of the work, the execution may fairly be said to deserve almost unqualified praise. The descriptive matter, though often couched in somewhat unconventional language, is clear and accurate, and the illustrations, nearly all of which are apparently drawn from the author's own sketches, are abundant, and what is better, are really illustrative. It would not be easy to find, throughout the whole range of electrical literature, more satisfactory examples of illustrative diagrams than those, for instance, on p. 24 explanatory of E M. F., or that on p. 222 showing the distribution of potentials in the Field quadruplex transmitter.

Mr. Maver has long been acknowledged to be a specially well-qualified expert in duplex and quadruplex apparatus, and accordingly the portion of the work relating to this subject is, as might have been expected, of unusual value to those having to do with these systems in ordinary practice. One cannot but be amazed at the marvelous flexibility of the quadruplex system, and the facility with which it lends itself to an infinite variety of special adaptations to meet the wants of the diversified service of the present day. A couple of dozen, more or less, of these modifications are described and figured, and these are obviously but types of many others that may readily be devised by the skilled quadruplex expert, whenever an exigency arises requiring it to be done.

Many special systems and pieces of apparatus of recent origin are described in this work, which may be sought for elsewhere in vain. In short, in spite of its somewhat unsystematic arrangement—a defect which is largely remedied by an excellent index—this treatise will be found to furnish a solution to no small share of the perplexing problems which continually arise in the every-day service of the telegraph.

We wish we might conscientiously praise the publisher's work as highly as we can that of the author, but a strict regard for truth compels us to express the opinion that the size and shape of the pages are inconvenient and awkward, and that the typography throughout is a conspicuous example of a certain indescribable lack of "style" which characterizes the productions of the rural printery; an odd jumble of different styles of captions; mixed fonts of type in the same caption; eccentricities of spelling which have passed undetected by the proof-reader, and so on. The excellence of the subject-matter, and especially of the numerous, beautiful and costly illustrations, might certainly have justified a far more elegant setting. Perhaps a desire to put the book within the reach of every operator, as shown by the price, may excuse this. But these minor blemishes, after all, detract but little from the solid merits of a work which must long remain a monument of the conscientious industry, unfailing grasp of his subject and painstaking fidelity of its author.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED MAY 24, 1892.

Accumulators :—

Manufacture of Electrodes for Secondary Batteries, J. F. McLaughlin, 475,535. Filed Jan. 31, 1890.

Relates to the method of applying the active material to the electrode supports and also in the formation of the electrode.

Alarms and Signals :—

Electric Signaling Apparatus, W. C. Moore, 475,334. Filed June 19, 1891.

An improvement in individual call apparatus.

Automatic Electric Alarm, F. S. Palmer and L. H. Delisle, 475,340. Filed Jan. 9, 1892.

An automatic heat alarm for journal bearings.

Conductors, Conduits and Insulators :—

Anti-Inductive Conductor, B. H. Wesslau, 475,648. Filed Jan. 21, 1892.

Employs an open net-work of threads of insulating material with air spaces between them and an outer envelope of insulating material covering the whole.

Dynamos and Motors :—

Commutator Brush, C. L. Coffin, 475,668. Filed Sept. 5, 1891.

A commutator brush consisting of strips of perforated sheet metal.

Lamps and Appurtenances :—

Electric Arc Lamp, L. Brianne, 475,289. Filed July 28, 1891.

A combination with a solenoid traversed by derived current of a movable armature sector, fly-wheel and rack.

Electric Arc Lamp, R. S. Dobbie, 475,544. Filed June 11, 1891.

An arrangement for increasing the intensity of an arc light by localizing the heat of the arc and for preventing the obstruction of the light by the gases produced by the arc.

System of Electric Lighting, M. J. Cowgill, 475,538. Filed Oct. 22, 1891.

A lighting system using a current of greater voltage than the rated voltage of the lamps which current is periodically forced through the circuit.

Incandescent Lamp Socket, C. A. B. Halvorson, 475,555. Filed Aug. 5, 1891.

A lamp socket adapted to be used interchangeably upon the various forms of incandescent lamps.

Electric Arc Lamp, J. E. Gaston, 475,727. Filed Sept. 4, 1891.

Has for its object to increase the reflecting power of electric head-lights and to simplify their construction.

Incandescent Electric Lamp, H. B. Meech, 475,698. Filed Nov. 10, 1890.

A series of incandescent lamps enclosed in a reflecting globe.

Incandescent Lamp Socket, F. C. Rockwell, 475,345. Filed Feb. 24, 1892.

A very cheap keyless socket attached directly to the lamp globe.

Incandescent Electric Lamp, H. Green, 475,391. Filed Aug. 22, 1891.

So constructed that a circuit may be formed with the filament through conductors in a recess in the neck of the lamp, without the aid of filling, etc.

Measurement :—

Electric Meter, A. G. McKenna and H. T. Weed, 475,411. Filed July 14, 1891.

Consists of an electrolytic meter-cell containing mercurial salt and having electrodes and receptacles for catching the deposited mercury.

Electric Actuator for Registering Mechanism, C. F. Holt, 475,393. Filed June 22, 1891.

Metal-Working :—

Device for Heating Metal Rods, A. D. Williamson, 475,651. Filed May 24, 1892.

An arrangement for electrically heating metal rods, etc., in close proximity with the tools employed in working them.

Hoop Welding Apparatus, C. L. Coffin, 475,667. Filed Apr. 25, 1891.

Miscellaneous :—

Electric Mechanism for Reciprocating Motion, H. S. McCay, 475,410. Filed Aug. 20, 1891.

Particularly adapted to drills or stone-cutting tools in which the armature is attached directly to the tool stock.

Coin-Controlled Electrical Apparatus, H. Wickham, 475,527. Filed Dec. 11, 1891.

Rheostat, C. Willms, 475,528. Filed Jan. 14, 1892.

Employs an adhesive resistance material containing finely divided conductive material and metal filings or the like.

Rheostat, C. Willms, 475,529. Filed Jan. 14, 1892.

Similar to 475,528.

Automatic Electric Time Check, C. K. Jardine, 475,566. Filed Dec. 10, 1891.

Claim 3 follows:

In an automatic time check the combination with the deflector of an electromagnet for operating the same and a clock provided with a circuit closer for operating the magnet.

Lightning Arrester, A. G. Waterhouse, 475,645. Filed Dec. 18, 1891.

A lightning arrester composed of three stationary flash plates, two connected at different points to the main circuit and the third to earth.

Cable Hanger, J. J. Nate, 475,600. Filed May 24, 1892.

Consists of a hook having a base which holds wires adapted to pass around the cable for the purpose of suspension.

Sealing Device, C. Cuttriss, 475,442. Filed Mar. 5, 1892.

A device for electrically melting sealing wax.

Amalgamator, J. M. Thompson, 475,360. Filed Jan. 12, 1891.

Lightning Arrester, J. E. Browne and F. H. Tidman, 475,482. Filed July 10, 1889.

A swinging ball lightning arrester.

Electrically Heated Sandbox, L. E. Pease, 475,703. Filed Nov. 16, 1891.

Railways and Appliances :—

Trolley for Electric Railways, J. W. Newhouse. 475,467. Filed Nov. 14, 1891.

Employs a housing intended to more firmly secure the trolley wheel and hold the ends of the shaft.

Switch for Overhead Wires, A. O. Hoyt & P. W. Leffler, 475,504. Filed Sept. 10, 1891.

Comprises a pair of discs detachably connected and each bearing a pair of opposite rail arms, constituting the trolley guide.

Electric Car Lighting System, J. F. McElroy, 475,514. Filed Dec. 19, 1891.

A system of car lighting by means of a dynamo operated by the motion of the car.

Station Indicator, R. B. Ayers, 475,378. Filed Dec. 3, 1891.

Station indicator designed to economize power and space.

Electric Locomotive, T. A. Edison, 475,491. Filed June 3, 1880.

Consists of a complete electromagnetic railway system embracing the generation, distribution and utilization of currents as motive power.

Electric Locomotive, T. A. Edison, 475,492. Filed June 9, 1880.

Electric motor for railways employing a supplemental grooved traction wheel adapted to grip the track.

Electric Locomotive, T. A. Edison, 475,493. Filed June 9, 1880.

A motor in combination with two derived circuits one including the rotating armature and the other the coils of the field magnet.

Electric Railway, T. A. Edison, 475,494. Filed June 3, 1880.

Claim 3 follows:

Combination with a section of main conductors of a short section thereof cut out of the main section and connected reversibly thereto by conductors arranged to reverse the direction of the current in such short sections.

Electric Motor Car, W. H. Patton, 475,702. Filed Sept. 7, 1891.

An electric car carrying a generator operated by a gas engine.

Telegraphs and Apparatus :—

Telegraphic Relay, C. Cuttriss, 475,441. Filed Dec. 1, 1891.

Employs a combination with a movable coil, of a divided local circuit, a distensible carbon spiral in each branch of the latter connected with a movable coil on opposite sides of the circuits and a receiving instrument in a bridge between the divisions of the local circuit. See THE ELECTRICAL ENGINEER, May 25.

Electrical Transmitting System, F. E. Now, 475,468. Filed Dec. 4, 1891.

Has for its object to create greater efficiency in the manipulation by a single operator of a number of separate telegraph circuits.

Telephones :—

Extension Transmitter for Telephones, V. A. Cook, 475,300. Filed Jan. 8 1892.

College Notes.

UNIVERSITY OF ILLINOIS.

ON May 19, an audience of two hundred and fifty listened to a lecture on the "Electric Transmission of Power." The speaker, Mr. George Cutter called special attention to the new phases of this subject which have followed the developments in alternating current working. Mr. Cutter had brought with him a collection of apparatus with which he repeated the induction experiments devised by Prof. Elihu Thomson, and in the course of his talk he showed their bearing on transmission problems of the future. The multiphase plant at Frankfort also came in for its share of attention, and the hearers were impressed with the grand outlook in this field.

WASHINGTON UNIVERSITY.

THE course in electrical engineering at Washington University, St. Louis, Mo., commences with the Junior year and extends through the Senior and one year of post graduate work. Even more than the usual amount of mechanical engineering is included in the course, and certain vacation work is also required. The electrical laboratory is well equipped and conveniently wired for experiments and tests.

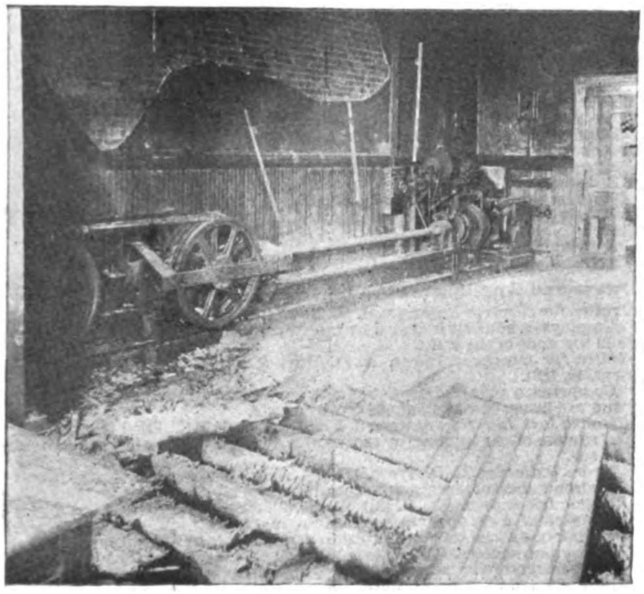
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Better is a large advertising account and much business, than false economy and poverty therewith.

THE SPRAGUE ELEVATOR AS A PHŒNIX.

A BRIEF note in our last issue called attention to the fact that a recent fire in the Cassidy Building, in this city, had burned through the fourth floor where the elevator is situated, and had created general havoc before it was got under control. The accompanying engraving—the reproduction of a photograph taken immediately after the fire—shows how intense the heat must have been; in fact, the elevator at first sight appeared to be completely disabled.



SPRAGUE ELEVATOR AFTER THE FIRE.

The insulation had melted from the wires, switches had burned off, the fuses were gone, the controlling cylinder was split, the regulating gear was stiff and somewhat distorted, and the whole machine blackened and clogged with mortar. Part of the machinery had been flooded. It was twelve o'clock before anything could be done towards removing debris, and at seven o'clock at night the elevator was in operation. It altogether seemed a remarkable test of reliability of electrical apparatus when well constructed and properly taken care of.

ENTERPRISE ELECTRIC CO.

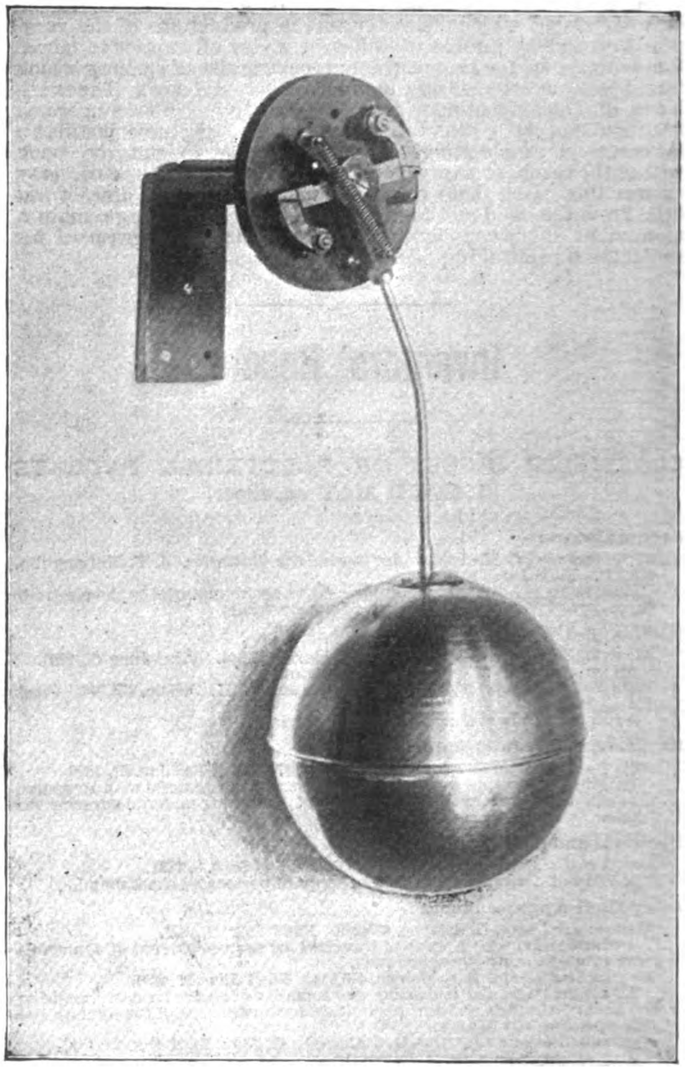
THE above-named company who are manufacturer's agents, mill representatives and wholesale distributors of electrical supplies of every description, have now got their handsome store in the Manhattan Building, 318-315 Dearborn street, Chicago, in order and are prepared to handle a large business in the most expeditious and efficient manner. They are agents for Day's Kerite wire, the fine quality of whose insulation is so well known and which recommends it to users of rubber-covered wire. They are also agents for the Western Electric Co.'s weatherproof line wire which is held in high appreciation by those who have used it, and also their electric light and house goods supplies, which are noted for their quality. In addition to these goods they carry a full line of Paiste switches, Bryant sockets, together with their porcelain goods and a full line of other high grade goods, among which are poles, cross-arms, brackets, oak pins, porcelain and glass insulators, porcelain goods, main line switches, underwriter's wire, and in fact all kinds of material for both inside and outside construction. They have made especial arrangements for making shipments with care and greatest promptness. Attention is called to their announcement in our advertising pages this week, and they will be pleased to receive correspondence from all interested in the purchase of supplies for telegraph, telephone, electric light or electric railway construction.

EDISON SWITCH FOR ELECTRIC PUMPS.

THE EDISON GENERAL ELECTRIC Co. has just designed and put on the market an automatic switch for use with electrically operated pumps employed in filling water tanks.

This is a simple single-pole switch with ebonite base, mounted upon an angle-piece and operated by a ball float. As the water rises in the tank, the ball float rises with it until it reaches a point where the switch is opened by the operation of a spring. The motor consequently stops and no more water is pumped into the tank. As the water is drawn off, the ball falls with the water level, the switch is closed, the pump starts and continues working until the tank is again filled to the desired point. The ball and other parts in contact with the water are insulated from the switch connections and line terminals, so that no part of the circuit can be grounded through the tank. The switch may be screwed to a wall or partition by the side of the tank, or, if convenient, may be placed within and screwed directly to one side of the tank.

The particular switch shown in the illustration is fitted with an arm 7 inches long, and a ball 7¼ inches in diameter, and will operate with a variation of 6 inches in the water level. It requires a space of 11¼ x 18½ x 20 inches, and can be used in any ordinary tank capable of holding more than thirty gallons.



EDISON AUTOMATIC PUMP SWITCH.

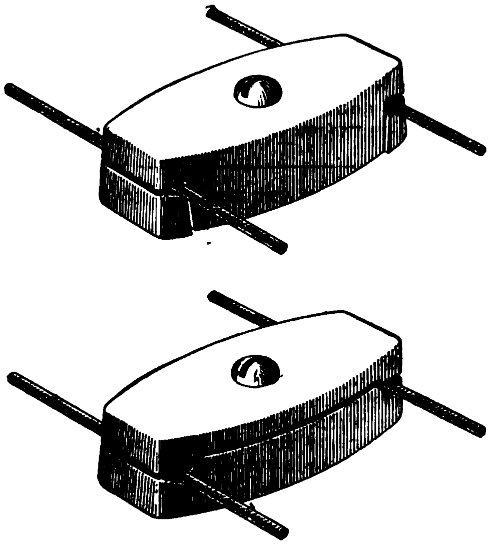
Switches of this type can be used in connection with motors up to 2 K. W. capacity, and can be arranged to operate upon any reasonable change in water level.

DETROIT ELECTRICAL WORKS.

THE above concern, of Detroit, Mich., has reduced its capital stock from $1,000,000 to $750,000. The latter amount has all been paid in.

THE SECURITY CLEAT.

The accompanying illustration shows a front and back view of the new "Security" cleat manufactured by the Security Insulator Co., of 136 Liberty street. The cleat is entirely novel in design, and is claimed to possess advantages over the old styles which will place it in the lead at once. It is made especially for incandescent wiring and, like the "Security" insulator, will hold a wire of any of the usual sizes. The construction of the cleat makes it very strong, and but one screw is needed. No kink whatever is made in the wire, and the insulation is not harmed in the least. It is made of the best vitrified porcelain, glazed or unglazed, and will, doubtless, prove a great convenience as an economizer of time and labor.



Security Cleat.

THE AMERICAN FEED-WATER HEATER.

The accompanying illustrations, Figs. 1 and 2, show the new American feed-water heater, the result of long practical experience in heater-building. It possesses many valuable features, and not a few novel ideas, which are claimed to give it some advantages over other styles. The coils are made of seamless copper tubing and are brazed to the gun metal fittings, thus eliminating, in a large measure, all liability to leak from bad joints. These fittings necessarily pass through the shell, and are threaded for the reception of the feed pipes, so that there are no joints inside the shell. The circular coils are perfectly smooth, have no internal obstruction and, consequently, very little internal friction. In designing these heaters, the area of the shell has been made considerably larger than the area of the exhaust pipe, so that it is not necessary to pass all the exhaust steam through the heater, though sufficient steam will always pass through on account of the vacuum created to raise the feed-water to 200° Fahrenheit. These heaters are well adapted to use with compound engines, increasing the vacuum and delivering the feed-water heated to the maximum degree. Fig. 2 represents a form of heater which is also designed for use as a purifier. It has a large water space unobstructed by tubes, and the conical shape of the bottom gives the mud or sediment a good opportunity to be effectually blown out. The top chamber can be readily taken off, being in no way attached to the steam or feed pipes, and the interior can be easily cleaned out. The coil can also be readily removed, and if coated with lime or other incrustation, easily cleaned and replaced at slight expense. From the peculiar arrangement of its connections, it can be at once cut off from the exhaust steam, or a limited amount of steam can be passed through it when desired, so that any temperature of feed-water can be procured. The coils are made of seamless copper, and the shell, as in the other heater, of cast iron or boiler steel.

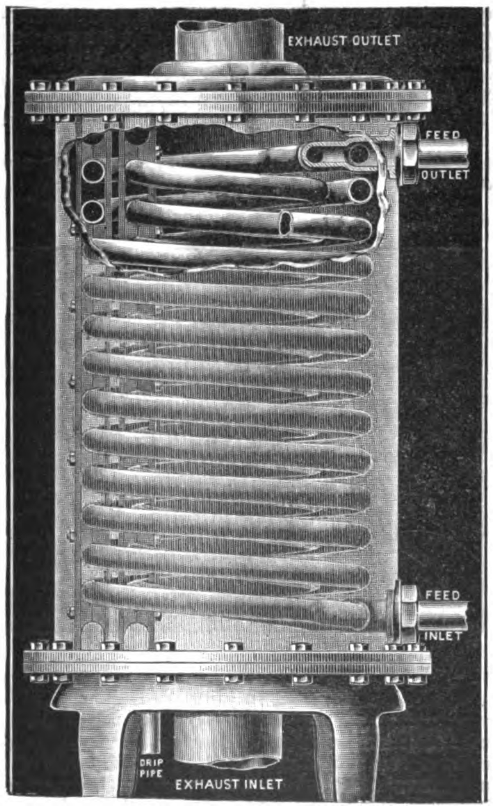


Fig. 1.—American Feed-Water Heater.

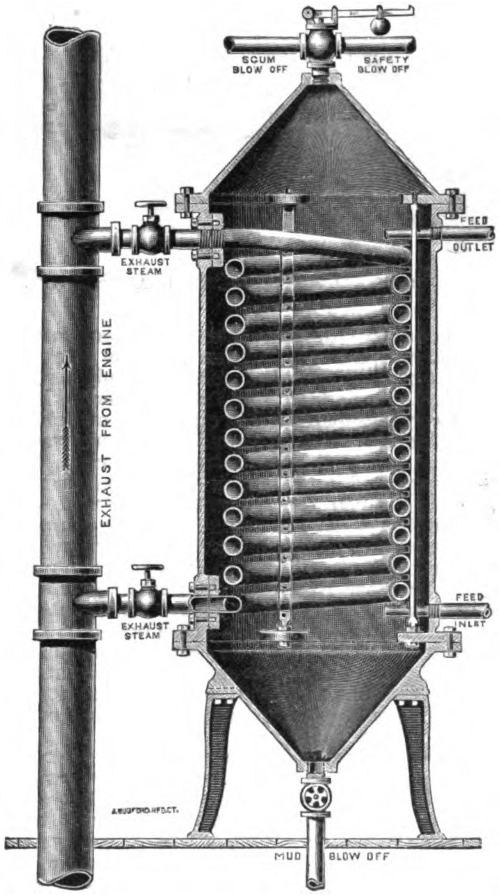

Fig. 2.—American Feed-Water Heater and Purifier.

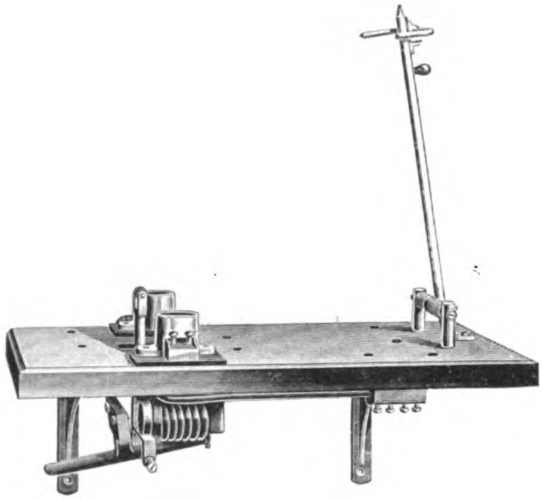
These heaters are manufactured by the Whitlock Coil Pipe Company, of Elmwood, Conn., who have a New York office in the Mail and Express Building, 203 Broadway, with Mr. John J. Finnell manager. The Jarvis Engineering Company, of Boston, are agents for New England, and have already installed several in the Eastern States, where they are giving entire satisfaction.

Mr. P. C. Ackerman, New York agent of the American Electrical Works, has just returned from a trip through the West, and reports a journey both remunerative and eventful. Mr. Ackerman chanced to be in the locality recently visited by the disastrous floods and had some thrilling experiences. In one instance a train upon which he was a passenger passed through a flooded district where the water actually reached the platform of the cars. An excellent trade and similar prospects are reported, the flood of orders being as high as the top floor of the factory.

THE STANDARD AUTOMATIC OVERLOAD SWITCH.

The Standard automatic overload switch shown in the illustration is designed to open quickly and positively and make a wide break so that a current of high potential can be broken in such a manner as to make it impossible to hold an arc. The length of the arm is about ten inches, while the switch opening is over one foot in length. The arm being thrown up by a strong spring, the break is made so quickly that the arc is broken with certainty.



Standard Automatic Overload Switch.

In order to compare the time taken to open this switch with that required to open a circuit by fuses, a fuse block was put in circuit with one of these switches wound and adjusted to open at one hundred amperes, and different fuses attached. It was found that with a twenty-ampere fuse in circuit the switch was invariably opened so quickly when one hundred amperes was thrown on that the fuse had scarcely sufficient time to warm. When a ten-ampere fuse was placed in the circuit both switch and fuse opened at the same time when the current was turned on. Clearly stated, this switch will open as quickly as a ten-ampere fuse will melt on a one hundred-ampere current. Similar fuses were previously tested and were found to open on currents indicated. The switch is so constructed that mechanical contacts are avoided by the use of mercury cups which insure good contact with perfect freedom of motion. The latch which holds the arm in place is thrown off by the armature of an electromagnet not connected to the latch, and perfectly free to move. The armature is heavy and has quite a distance to travel, so that when it reaches its magnet a heavy blow is given to the latch insuring certain liberation of the switch arm.

These switches are claimed to open within one per cent. of the current to which they are adjusted, whether the current is raised quickly or slowly, and to do their work so quickly that even on a short circuit the load cannot become heavy enough to throw off belts or damage machinery. They are made by the Electro-Dynamic Co., of Philadelphia, who wire them for any current from an arc-light circuit to the heaviest power generator.

AN ILLUMINATING ELECTRIC "SPELLER."

At the recent graduating exercises of the Columbia University Law Class, '92, a very pretty and novel effect was obtained by the aid of what has been termed the electric "speller." This is nothing more or less than a machine which spells words, and even can be made to construct entire sentences. It consists of any desired number of boxes, ranged side by side, and made light-tight, except in front, where they are covered with letter transparencies cut from ordinary cardboard, and having different colored tissue paper pasted over them to give various colors, if desired. In each box is a 16 c. p. lamp. The "speller," which is driven by a C. & C. ⅛ h. p. motor, makes about eight revolutions a minute. It is a cylinder about 14 inches in diameter, around which are placed any desired number of brass strips. The first strip goes completely around, each of the others being two inches shorter than the next one adjoining. From one end of the cylinder to the other, and connecting with the strip that goes entirely around, is another strip to which all the others are connected. Independent brushes carry the current to each strip.

During the graduating exercises above referred to, which were held in the National Theatre, in Washington, D. C., the lamp-boxes were arranged in the shape of an arch suspended above the stage. First flashed out the letter C in orange; next the letter O in blue (these being the colors of the University), until the entire sentence, "Columbia University Law Class '92" was presented in bright colors. After being lit for about fifteen seconds all the letters simultaneously went out, only to be repeated again at the will of the operator. The "speller" can be made to do its work backward or forward by a reversing switch. By the addition of smilax, vines and flowers, with a sprinkling of electric lights artistically arranged, the effect can be made very beautiful.

This machine was designed and built by the Washington Construction Co. for decorative use in the many entertainments that Washington is noted for. We are indebted to Mr. Messner of this firm for a description of this interesting device.

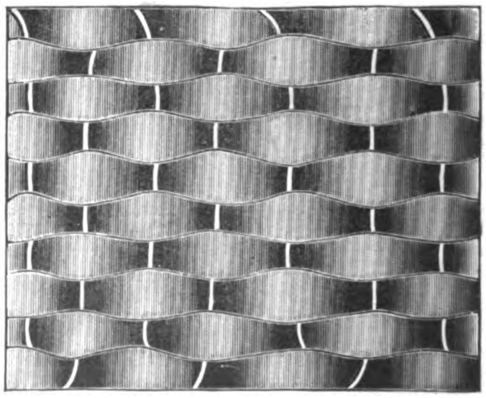
A SHORT RAILWAY PLANT FOR GRAND RAPIDS, MICH.

It is safe to say Mr. James R. Chapman, general manager of the Consolidated Street Railway Co., Grand Rapids, Mich., is one of the best satisfied men operating an electric road. Mr. Chapman has from the first been an enthusiastic believer in a "gearless" street car motor. He placed a large order for these motors with the Short Electric Railway Company, of Cleveland, Ohio, several months ago, and on Sunday, May 22d, the first gearless car was run over his lines. Two trips were made by a large party; one in the morning taking that portion of Grand Rapid lines having grades of from three to five per cent. Later in the day the car was run over the steepest and most difficult sections of track in the system, where it was demonstrated to the satisfaction of every one that the "Gearless" is a first-rate hill-climber. The car ascended one 9½ per cent. grade at a speed of nine miles an hour without the least difficulty. This run was made several times in succession; the car being stopped and started in the middle of the grade with as much ease as on level track. The speed attained on the level was surprising to those accustomed only to cable cars and to the rates attained with the average geared electric motor.

The Short Company manufacture two types of gearless motors; one for high speed on level track, the other for slower speed on grades. The Grand Rapids motors will be of the latter type, owing to the stiff grades on the road, but will make twenty-five miles per hour easily on the level.

THE BRIGGER PATENT WOVE LEATHER BELTING.

The Brigger Belting Company, of Akron, Ohio, are placing on the market a belt entirely different from any other at present made and one that is said to be giving the best of satisfaction. Those acquainted with the manufacture of leather belts are well aware that certain portions of a hide will stretch badly. The Brigger Belting Company, however, claim to have obviated this trouble by a process similar to the ordinary weaving of a piece of cloth. The finished product is shown in the accompanying illustration. Strips of leather cut to a certain width and submitted to a special stretching process are placed on a loom and form the warp, the woof consisting of very strong twine treated chemically. Any width and any length is thus possible. After the belt is woven exactly to the width required, it is taken from the loom, placed on a single facing of leather of the same width and fixed there by a cement, which is also a production of this company, at a pressure of about 15,000 pounds to the square inch.



Brigger Patent Wove Leather Belting.

The Brigger Belting Company though not old, have succeeded in placing a large number of belts in different parts of the country and are in receipt of a great many excellent testimonials. The works are situated in the lively manufacturing town of Akron, Ohio, where the company have large landed interests.

THE ELECTRIC LAUNCH "ELECTRA."

AMONG those who have had an abiding faith in the success of electric launches is Mr. Fred. Reckenzaun, who, in an article published in the ENGINEER some time since, showed that a profitable business awaited those who should undertake the systematic exploiting of this field. Mr. Reckenzaun's figures were based on the results of actual experience, and many of our readers will recall the "Magnet" which was built and operated by Mr. Reckenzaun in New York Harbor and adjacent waters. This little vessel has since been sold to the Pacific Coast, where, after several years of duty, it is still in excellent condition.

More recently the subject of providing electric launches has been taken up by the Electric Launch & Navigation Co., of this city, of which Gen. C. H. Barney is the general manager and Mr. Fred. Reckenzaun, the electrician This company has just finished the construction of an electric launch called the "Electra," which is now being run on the Passaic River at Newark, N. J., and at the invitation of the company, a party of gentlemen representing the electrical press last week enjoyed the privilege of a sail up the Passaic.

The "Electra" is 34 feet long, 6 feet beam and draws 28 inches of water, and is able to accommodate comfortably from 15 to 20 passengers. She is equipped with a 4 h. p. series wound Reckenzaun motor, having a Gramme ring armature, and the fields of which are entirely of wrought iron, being built up of parallel bars. The armature is directly connected to the screw shaft made of Tobin bronze; the thrust is taken up by a ball bearing running in oil. The motor weighs 420 pounds.

The motive power consists of 78 cells arranged in two sets and having a capacity of 125 ampere-hours; each cell weighs 38 pounds. The controlling switch which was designed by Mr. Reckenzun is mounted on a shaft concentric with but independent of the steering wheel, so that the helmsman has perfect control over the vessel with the least possible effort.

With the motor running at its normal rate of 650 revolutions per minute, a speed of about seven miles an hour is obtained which can be maintained for 10 hours, thus giving the boat a traveling distance of 70 miles without recharging the batteries. Four different speeds are obtainable, viz., 3, 7, 9 and 11 miles per hour.

It is interesting to note that the storage cells are operated with gelatinous electrolyte which Mr. Reckenzaun has found to be almost indispensable in electric launch work, as it obviates completely all splashing and spilling of the solution as generally employed, and leaves the vessel without a trace of the odor of acid.

The behavior of the "Electra" is admirable in every way; the vibration due to the screw is almost inperceptible and there is an entire absence of those vibrating shocks inevitable with even the smoothest running reciprocating engine.

Negotiations are now in progress by the Electric Launch & Navigation Co., to introduce their boats on the lagoon and lakes at the Chicago World's Fair, and it is to be hoped that they may prove successful.

ROPE DRIVE TRANSMISSION.

THE Hotel New Netherlands at the corner of Fifth avenue and 59th street will contain, when completed, one of the most powerful rope drives for electric light and power purposes in the country. There will be one 200 and one 300 h. p. drive from Armington & Sims engines to jack-shafts, one of 120 h. p. from engine to dynamo, and four of 120 h. p. from jack-shafts to dynamos. The rope used from engines to jack-shafts is that known as Lambeth cotton, made in Manchester, England, and especially imported for this installation, while raw-hide rope will be used on the dynamo drives. The sheaves are of the built-up pattern, capable of having extra grooves added at any time.

The Link-Belt Engineering Company of Nicetown, Philadelphia, and 49 Dey street, this city, to whom the contract has been awarded, have *carte blanche*, and will make the plant a model one in every respect. We may add that, in conformity with the rule of the hotel, the sheaves, etc., will rejoice in a costume of "baby" blue with gold stripes.

THE RAILWAY EQUIPMENT CO.

THE RAILWAY EQUIPMENT COMPANY, Chicago, reports business as rushing in all departments. They have added largely to the established business of the Electric Merchandise Company, whose business they purchased some few weeks since. Owing to the fact of the standard appliances of this company having such an established reputation, a very large number of late contracts for equipment have been made with the understanding that such appliances will be used.

The company reports a largely increased business over the last season, but having increased its manufacturing facilities, it is able to guarantee immediate shipments. The managers of the company having devoted their entire time and attention to "electric railway supplies only" for several years, are prepared to furnish reliable and complete information to parties about to equip electric street roads. Such inquiries are given the most careful attention, are answered fully and without charge.

MICA ASBETITE.

THE ELECTRIC APPLIANCE COMPANY report having closed arrangements with the Mica Asbetite Insulating Company to represent them in the Western market and carry a large and complete stock of their goods in Chicago. Mica Asbetite is possibly the latest insulating compound in the market for electric railway use, although not new, as it has been in use for some considerable time on some of the largest lines in this country, and the wonderful results that have been obtained has led the Asbetite company to decide to take an active part in electric railway work and push their goods to their proper place in the front rank. The Mica Asbetite compound is unaffected by heat, in fact the appliances are subjected to a heat of over 800 degrees in the process of manufacture. The compound resists water perfectly and the bells can be soaked in water or even acid for any length of time without affecting the compound. The Electric Appliance Company claim to have the coming insulation for railway work, and an examination of the material seems to substantiate their claim.

POWERFUL TURBINES FOR NIAGARA.

THE immense new pulp and paper plant of the Cliff Paper Co., at Niagara Falls is to be supplied with late new designs of the horizontal shaft double-discharge James Leffel wheels, built by James Leffel & Co., Springfield, Ohio. The contract for this work was signed, after the Cliff Co. had made a full and careful investigation, of the merits of various wheels presented during the past year for their consideration. Each of these turbines is to be 1,100 h. p. capacity; and built essentially upon the plan of their style No. 23, illustrated in the pamphlet of James Leffel & Co. These wheels will connect directly to the pulp grinder shafts at each end of the wheel shafts, without belts or gearing.

This water-wheel company has celebrated its thirtieth year of continuous business in this line of work. They have added many improvements, to their James Leffel wheel in the past two years; and have designed a large number of new styles, incorporating in them the best ideas of their large experience. The manufacturing plant of this company, has also been recently greatly extended; and various pieces of new, improved, and heavy machinery added; all adapted to the heavy water-wheel work they are now manufacturing. They shipped some time since one James Leffel wheel and casing weighing forty-five tons; also filled one order for nineteen large wheels for one pulp and paper company.

QUICK RACE REPORTING IN ENGLAND.

WITH regard to the very quick reporting of the Oxford and Cambridge boat race on the Thames, recently mentioned in our columns, it should be stated that this feat was due to the enterprise of the Exchange Telegraph Co., Ltd., of London, from whose boat a cable was paid out so that no time was lost in sending news of each stage of the great contest.

AN EXHAUST STEAM PLANT FOR CEDAR RAPIDS, IA.

THE CEDAR RAPIDS, IA., ELECTRIC LIGHT AND POWER COMPANY has contracted with the American District Steam Company, of Lockport, N. Y., for the construction of about one mile of 12, 10, 8 and 6-inch steam mains, to be used for the distribution of exhaust steam for heating dwellings, offices, stores and public buildings in that city.

THE PREMIER ELECTRIC MOTOR.

THE PREMIER ELECTRIC Co., of 17 and 19 Whipple street, Brooklyn, have sent us the following communication:

BROOKLYN, N. Y., May 25, 1892.

WE desire to state publicly "through the columns of THE ELECTRICAL ENGINEER," that we have the sole right to manufacture electric motors, under Letters Patent 321,049 June 30, 1885, and that Mr. Wm. S. Pendleton, of the Premier Electric Co., is the sole owner of the above patent, which fully covers the use in a motor, of an armature having three poles as connected to make a self-starting motor. We are prepared to fill the wants of the trade and manufacturers; and the trade at large are hereby warned against the manufacture or sale of motors, having this armature "other than our manufacture," as all infringers will be prosecuted.

Very respectfully yours,
THE PREMIER ELECTRIC CO.,
By ELMER F. KELLY.

THE PURITY OIL FILTER MANUFACTURING CO.

THE following is an abstract from a letter recently received by the above company, that speaks for itself:

We pour into the No. 4 Ideal Steam Oil Refiner every 24 hours about 10 gals, of dirty oil and draw out an equal amount of purified oil which seems to be excellent for all uses about the Rod Mill engine except for cylinders, and moreover, we find we can substitute the purified oil for the more expensive lard oil which we have hitherto deemed it necessary to use on the crank pin and crosshead slides.

NEW CASTLE (PA.) WIRE NAIL CO.
Edward King, vice-president.

MR. F. S. TERRY, general manager of the Electrical Supply Co., of Chicago, has returned from a business trip East.

NEW YORK NOTES.

The Short Electric Railway Company report orders for additional apparatus from the Bloomington City Railway Company, Bloomington, Ill., ten 40 h. p. single-reduction equipments and one 100 h. p. generator; South Covington and Cincinnati Street Railway Company, four 40 h. p. single-reduction equipments; Schuylkill Electric Railway Company, Pottsville, Pa , four 50 h. p. single-reduction equipments; West End Street Railway Company, Rockford, Ill., six 20 h. p. gearless equipments; Georgetown and Tenallytown Railway Company, Washington, D. C., two 40 h. p. single reduction equipments; Wilkesbarre and Wyoming Valley Traction Company, Wilkesbarre, Pa., three 60 h. p. single-reduction equipments, one 200 h. p. generator; and the Braddock Electric Railway Company, Braddock, Pa., one 40 h. p. single-reduction equipment. They have also closed contracts recently with the Baltimore Traction Company, Baltimore, Md., and the Janesville Street Railway Company, Janesville, Wis.

The Jersey City and Bergen Railroad Company, of which Mr. C. B. Thurston is president. has just closed an important contract with the Ball and Wood Co., of New York, for three of their improved cross-compound engines of 300 h. p. each. The engineers of the Pennsylvania Railroad have carefully investigated eight leading makes of engines, which were in competition for this contract. The intention of the company is to make the plant which will operate its lines a model one not only in respect to the latest and most approved type of engines but in its other equipment and arrangement.

Short Electric Railway Co.—The Philadelphia agency has been consolidated with the New York and Mr. Wm. Hazelton, 3d, has removed to Cleveland, Ohio. Messrs. S. L. Nicholson and Frank R. Ford will be located at the New York office as agents. A great deal of attention has been given to the work of the Short Co. by the New York papers during the past week, owing to the announcement that Prof. Short is ready to grapple with the problem of running the Third Avenue Elevated Road by electricity.

The Crescent Insulated Wire and Cable Co., of Trenton, N. J., suffered from a fire in its factory, last month. The roof and fourth floor of the structure were completely destroyed. The company write us: "The loss from our enforced stoppage, though for a brief period only, will be considerable, as we have been for the past three months taxed to our utmost capacity and far behind our orders. We hope to be able to resume running full in about two weeks."

A Correction.—The E. S. Greeley and Co., write us that Mr. Ralph A. Schoenberg, who was recently reported to be representing that concern, has no connection with it whatsoever, and that his recent business trip was made entirely in his own behalf.

Mr. Eugene Phillips, president of the American Electrical Works, was a New York visitor last week and called at the new headquarters of The Electrical Engineer.

NEW ENGLAND NOTES.

The Redding Electric Company, of Boston, have recently been doing an excellent business in watch-clocks, and last week received orders for no fewer than twelve complete clock equipments. As is well known, their clock is the only one which gives a plain printed record, a fact which seems to be telling largely in their favor as they become better known. These twelve clocks ordered are going to the following cities: Denver, Col., Provo City, Utah. Huntington, W. Va., New York City, Pittsburgh, Pa., Syracuse, N. Y., Evansville, Ind., Lexington, Ky., Jackson, Mich., and three to Mexico.

The Consolidated Electric Manufacturing Company, of Boston, are in receipt of an important order for Heymann arc lamps from Central America, which they received direct from an illustrated article in a recent issue of The Electrical Engineer. The purchaser wrote saying, "The article in The Electrical Engineer caught us dead." The Consolidated Company are extremely busy in this line of work, and judging by the number of orders which they have received for the "Heymann," it seems to have taken the public and to be giving satisfaction.

The Westinghouse Electric Company have sold, through Mr. R. S. Brown, their New England agent of the railway department four car equipments to the Natick and Cochituate Street Railway Company of Natick, Mass. This road has previously been operated by horses, but will now be changed over into an electric line, and will be extended to Saxonville, a distance of about 10 miles. There will be one motor on each car of 25 h. p.

The Thomson-Houston International Electric Company, whose headquarters have hitherto been at 620 Atlantic avenue, Boston, will remove their offices about July 1st to larger and more commodious offices on the eighth floor of the Edison Building, New York City.

Mr. Francis R. Hart, of the Massachusetts Electrical Engineering Company, of Boston, has just returned from a three months' business trip in Jamaica and the Republic of Colombia, and has a few real Mexican cigars to regale his friends with.

Mr. James H. Mason, general manager of the Simplex Electrical Company, of Boston, has just returned from a four weeks' trip in the West, and is well pleased to find that Simplex still finds hosts of admirers in that section. Some of the largest buildings in the West are wired with Simplex, and the good record which they have given is inducing many more architects to adopt it for a thoroughly good safe insulation.

The Pettingell-Andrews Company, of Boston, have just added another useful specialty to their long line of goods in the shape of the P. A. blow lamp. This lamp is used for soldering line work both inside and outside of doors, and is also largely used by painters for scorching off old paint. It is quite different in design from all other blow lamps in the market, and should be of interest to all wiremen.

Albert & J. M. Anderson, of Boston, are in receipt of their first order from Mr. Blackwell, their London agent, for the line equipment of an electric street railway, and are congratulating themselves that "Ætna" seems to have caught the British public. They have just appointed Messrs. J. C. White & Co, of St. Louis, Mo., as their agents for line material in that territory.

The Eastern Electric Light and Storage Battery Company, of Lowell, Mass., are furnishing a tested fuse wire in all size from 8 to 100 amperes, in one-pound spools. This wire is made from a special alloy, and each size is guaranteed to carry the current marked on the spool, and bears a certificate of the company to that effect.

WESTERN NOTES.

Mr. Thos. G. Grier, Western manager for the Bryant Electric Co. has removed from 427 the Rookery Building to 1522 Monadnock Building, and is now settled in his new office. Mr. Grier for the past year has been managing the H. T. Paiste business in the West. The Bryant Electric Co. have purchased the patents of the Paiste single-pole switch. In addition to the other specialties manufactured by the Bryant Electric Co., Mr. Grier will handle the Paiste single-pole switch. The Bryant Electric Co. have also purchased the absolute control of the K. W. rosettes and cut-outs.

Mr. W. L. Silvey, of the Dayton Manufacturing Co., Dayton, Ohio, recently shipped two carloads of his No. 30 storage battery to the C. & O. railroad for train lighting work, and he has also unfilled orders for four carloads more. He is making these batteries in three different sizes and among other uses to which they are being put is the lighting of horse street railway cars, which is somewhat of a new departure. He has recently furnished a set to H. Ward Leonard, of New York, to be used for testing purposes.

Mr. Gilbert M. Smith, manufacturers' agent, 925–927 Unity Building, 79 Dearborn street, Chicago, announces that he will represent directly at that place a few leading makers of brass and copper bare and insulated wire, hardware specialties, etc. Mr. Smith has had eleven years' experience with the Ansonia Brass & Copper Co. and for the past four years acted as manager of their Chicago branch.

Mr. H. G. Osburn, who has been connected for some time with the Edison General Electric Co., has resigned his position and associated himself with the Bain Electric Mfg. Co., to look after the selling part of their business. Mr. Osburn, with his pushing qualities and apparatus so well known as the Bain, will undoubtedly largely increase that business.

Mr. John R. Markle, financial and fuel gas, steam and electrical expert, of Detroit, Mich., was a Chicago visitor last week and called at the office of The Electrical Engineer. The Western office of The Electrical Engineer was also favored by a call from Mr. E. H. Cutler, manager of the Elektron Mfg. Co., Springfield, Mass.

Mr. J. H. Cooke, manager of the Chicago office of the Buckeye Electric Co., reports that since May 1, their orders for Buckeye incandescents have far exceeded their most sanguine expectations and that their coiled filament lamp is in great demand.

Mr. W. S. Mullen, of the Union Electric Co., 45 Broadway, New York, manufacturers of storage batteries, spent a few days in Chicago last week.

Mr. R. Humffreys-Roberts, secretary and manager of the Fontaine Crossing Co., Detroit, Mich., spent a few days in Chicago last week.

THE
Electrical Engineer.

VOL. XIII. JUNE 15, 1892. No. 215.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—VI.[1]

BY

A. E. Kennelly

RELUCTANCE.

IN order to determine the flux in a magnetic circuit, we might, in accordance with results thus far obtained, proceed to find the distribution of potentials (assuming that such existed), from this, the gradient B, and then calculate the surface integral of B over an area drawn once across the circuit. But there is another method more direct and comprehensive, which will enable the flux to be found, ideally, at least, if not practicably, and that is, by determining the total *reluctance* in the circuit. This reluctance, divided into the M. M. F., gives the flux as quotient. Reluctance is thus the analogue in the magnetic circuit, of resistance in the galvanic, with the distinction already referred to in Part I, that while resistance checks the flow of current, it exchanges the electrical into thermal energy, while reluctance acts as a regulator of flux only.

We are now enabled to apply Ohm's law to the magnetic circuit in the form $F = \frac{M}{R}$, where F is the flux, M the M. M. F., and R the reluctance of the circuit.

Simple as is the rule, and easy of recollection by its analogy to the fundamental law of the galvanic circuit, it very frequently fails in practical application, owing to the difficulty in detail with the calculation of reluctances. This is incidental to the fact that there is no known magnetic insulator. Resistances in the galvanic circuit are usually easy to determine numerically, for they commonly belong to wires, which are uniform cylinders or are considered as such. Magnetic paths are, on the contrary, almost always divergent and irregular.

The problem of finding the reluctance of a circuit is generally similar to that of finding the joint resistance of a bundle of metallic wires all connected in parallel, whose lengths are variable, and whose individual cross-sections differ from point to point. Apart from this numerical difficulty, the determinations of reluctance and resistance are essentially alike. A substance would have unit specific resistance or resistivity, when a block of it one centimetre cube, would offer one unit of resistance between two metallic plate electrodes pressed against opposite faces. A M. M. F. of unity, separating two opposed parallel faces one centimetre apart, would establish unit intensity in the intervening space, because the gradient of potential would evidently be one erg on the unit pole per centimetre, for which one C. G. S. line of flux will be accorded to every square centimetre of surface. In other words, unit reluctance is that of one centimetre cube of space in the air-pump vacuum. In reality the difference between the reluctance of space in the exhausted air-pump receiver, and that of wood, copper, flint, and nearly all substances except the magnetic metals, is so small that it may be practically left out of consideration.

As an example of applying the principle of reluctance to magnetic circuits, let us consider a closed circular solenoid of the anchor-ring type, already discussed in Chap. IV. Let the cross-section of the ring have any shape, and an area of a square centimetres. Also suppose the mean radius of the ring to be r centimetres, and r to be so large compared with the ring's thickness that the intensity which we know to be greater at the inner and lesser at the outer circles, may be taken as uniform through the ring without sensible error. The winding is to have N turns, and through these a current of c units is to circulate. Then for each centimetre of magnetic circuit, there will be a square centimetres in parallel, giving a reluctance per centimetre of path $= \frac{1}{a}$, and since the total length of circuit (a circle of radius r) is $2 \pi r$, the total reluctance will be $\frac{2 \pi r}{a}$. The M. M. F. is 4π times the current turns on the ring, or $4 \pi N c$, and the flux $= \frac{4 \pi N c a}{2 \pi r} = \frac{2 N c a}{r}$, the result obtained in Chap. IV.

As an example, let the ring have a mean radius of 50 cms., and a section of 5 square cms. If uniformly wound with 1,200 turns of thin wire carrying a current of two amperes, or 0.2 C. G. S., the M. M. F. will be

$$4 \pi \times \tfrac{2}{10} \times 1{,}200 = 3{,}016;$$

and the reluctance $\frac{2 \pi \times 50}{5} = 6.2832.$

The flux will thus be $\frac{3{,}016}{6.2832} = 480$, and the mean intensity $B = \frac{480}{5} = 96.$

Closely related to the conception of reluctance, is another, often very useful, *permeance.*[2] The two are mutually reciprocal. Reluctance having its galvanic analogy in resistance (ohms), permeance represents conductance (mhos). The flux in a circuit is the M. M. F. multiplied by the permeance, and if we represent the latter by the symbol P,

$$F = \frac{M}{R} = M P; \text{ so that } P = \frac{1}{R}, \text{ or } R = \frac{1}{P}.$$

The permeance of a conducting channel in which the lines of flux are parallel, would be the area of the channel in square centimetres, divided by the length in centimetres; but as such uniform channels are rarely encountered, the permeance has to be found by supposing the actual channels divided into a large number of short columns, comprised between successive equipotential surfaces, determining the permeance of each lamina separately, and afterwards compounding them in series.

As an instance of the application of permeance and its principles, to the determinations of magnetic circuits, we may consider the case of a closed, circular solenoid whose cross-section is too large, relatively to its radii of revolution, for the assumption of a uniform intensity everywhere within. We will suppose that its section is rectangular, as shown in Fig. 14, with sides parallel to the axis of revolution. Let the radii be R and r, and the height h. Also, let the winding layer be so thin that the amount of flux in the substance of the conductor need not be considered. As before, the M. M. F. will be $4\pi Nc$. The mean path of the flux will be greater than $2\pi r$ and less than $2\pi R$; but it will not be the arithmetical mean of these two limits, because the flux is denser at the inner portions of the section. By dividing up the section into a large number of thin rings such as that represented between the radii ρ and $\rho + d\rho$ we may find the permeance of each separately, and then sum them all for the total permeance. The permeance of the thin ring indicated will be its area $h\, d\rho$ divided by its length or $2\pi\rho$, and we have to sum all these terms between the radii r and R; this is given by the integral

---

[1] *Copyrighted* 1892, *by A. E. Kennelly.*

[2] Silvanus P. Thompson, "The Electromagnet," page 178.

$$P = \frac{h}{2\pi}\int_r^R \frac{d\rho}{\rho} = \frac{h}{2\pi} \log_e \frac{R}{r}$$

representing the total permeance.

The flux in the solenoid is

$$F = 4\pi Nc\, \frac{h}{2\pi} \log_e \frac{R}{r} = 2\, Nch \log_e \frac{R}{r}$$

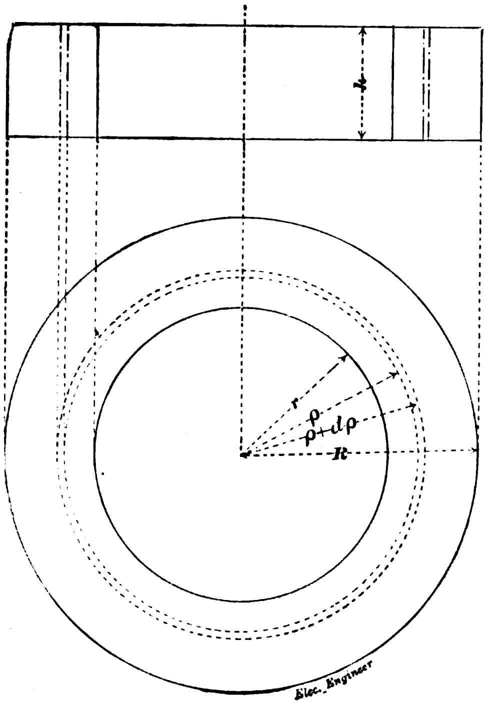

FIG. 14.

This will be the formula to employ for a closed circular solenoid of rectangular section, when the simpler expression already given is not sufficiently accurate for the purpose in view.

As an illustration, let $R = 15$ cms.; $r = 10$; $h = 5$; and $N = 500$, with $c = 1$ ampere or 0.1 unit; $M = 4\pi \times 500 \times 0.1 = 628.3$.

The permeance

$$P = \frac{5}{6.2832} \times \log_e \frac{15}{10} = 0.3227,$$

so that $F = MP = 628.3 \times 0.3227 = 202.8$ with a mean

$$B \text{ of } \frac{202.8}{25} = 8.112.$$

If we had been content to employ the previous formula, with a mean radius r of 12.5, and a cross-sectional area of 25 sq. cms., we should have obtained

$$F = \frac{2 \times 500 \times 0.1 \times 25}{12.5} = 200,$$

and the mean $B = 8.0$; or we would have underestimated the flux by about 1½ per cent.

Although the difficulties that beset the numerical determination of reluctances are generally prohibitive, the ideas it embodies and suggests are often valuable in dealing with magnetic circuits. Thus it is evident that the flux through a single circular turn of wire carrying nc amperes must be greater than that through a long solenoid of the same diameter, having n turns through which a current of c amperes circulates, for although the M. M. F. in each magnetic circuit will be the same, there will be, roughly speaking, an additional reluctance in the solenoid of $\frac{l}{a}$, where l is its axial length and a its cross-sectional area, besides that due to a longer exterior path. For a given number of turns, short coils of large area emit the greatest flux. Practice in the measurement of magnetic circuits trains the eye to form an estimate of the flux that a coil will emit, per ampere of circulating current. The conditions for the maximum total flux are often adverse to the development of a high intensity.

Permeances vary directly, and reluctances inversely, with the linear dimensions of a geometrical system of conductors. Suppose that any arrangement of coils or wires is fixed in space, and that a steady current is flowing through them. If we imagine all the equipotential surfaces properly described, the values of the intensity and of the flux in the circuits or combination of circuits will be definitely determined. Then if the linear dimensions of the whole system be suddenly increased, or diminished, in a given ratio—if its scale of construction be altered—the permeances of each circuit, or corresponding portion of a circuit, will have been altered in the same ratio. If the scale had been increased three times, the relative arrangement of equipotential surfaces will not have been affected by the change, but corresponding distances being everywhere trebled, the gradient of potential will be three times less. The lessened intensity will, however, be carried through areas that will be all correspondingly increased nine times, and the aggregate flux will therefore be three times as great as in the original. Or, from the point of view suggested by the conception of permeance, each elementary path of flux will have been lengthened three times, but enlarged nine times in cross-section, so that its reluctance will be three times less and its permeance three times more.

Consequently, if the flux is once determined for a magnetic circuit, it increases directly with the dimensions or scale. This implies that the diameter of the conductors is altered in the same proportion. With this assumption, the flux in a circuit of a given form, number of turns, and current carried, will be proportional to the length of wire it contains.[3]

A NEW SUBWAY COMMISSION FOR BROOKLYN.

MAYOR BOODY has appointed Prof. George W. Plympton and Frederick R. Lee as the two members of the new Brooklyn Electrical Subway Commission provided for in a bill signed by Governor Flower recently. The measure was drawn by the local electrical companies, and the $3,000 a year to be paid to each commissioner, in addition to the running expenses of the commission, will be raised by these companies. Prof. Plympton was a member of the old Subway Commission, and has charge of the Scientific Department of the Polytechnic Institute. Mr. Lee is a lawyer and has been prominent in all the independent Democratic movements of recent years.

ELECTRIC POWER ON A STEAM ROAD.

ONE of the first experiments in the country in using electricity in place of steam on a standard gauge railroad will be made at Ellwood, Pa. H. W. Hartman is going to introduce it on one of his roads, the Beaver and Ellwood, from Ellwood to Ellwood Junction, a distance of three miles from Pittsburgh, where it connects with the Pennsylvania lines and the new bridge crossing the Beaver River, and connecting with the Lake Erie Railroad. The electric cars will be run over the same road and rails used by the present steam line.

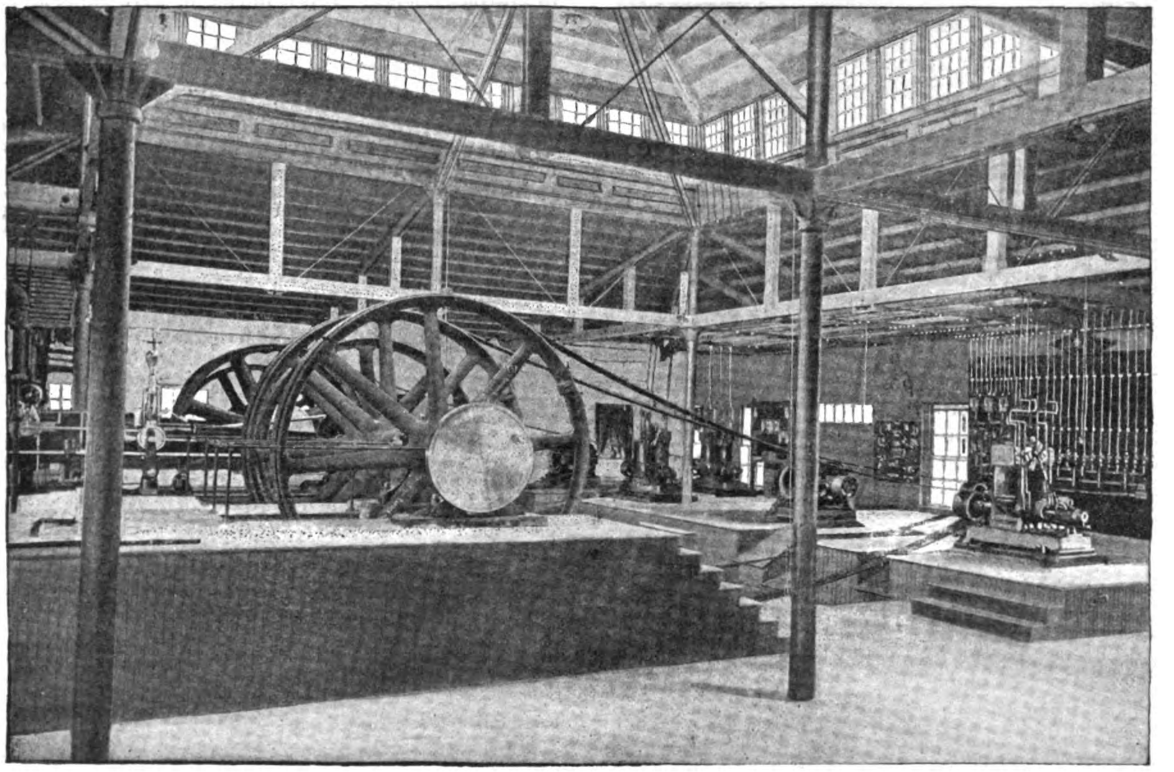
[3] *Vide* a paper by Carl Hering before the Franklin Institute, May, 1892.

THE NEW EDISON PLANT AT NEWPORT NEWS, VA.

AS IN nearly all cities in the Union laying claim to commercial importance, electricity has been called in to play its part at Newport News and a short description of the Edison plant erected there will prove of interest.

Recently a company was formed to light the town on a more comprehensive scale than it had been hitherto. This company, the Peninsula Electric Light Company, began work at once by introducing the Edison three-wire system of distribution for incandescent lighting. The two arc machines forming the plant of the old company were purchased by the new one and set up in the new station, and to the Edison General Electric Company was confided the entire work of installing the new station.



THE NEW EDISON PLANT AT NEWPORT NEWS, VA.

At the outset it was computed that two 45-kilowatt Edison compound-wound dynamos would suffice to meet the demand, but before the work of putting in these was completed, the Peninsula Company found the demand increasing so largely as to necessitate the installation of two additional 45-kilowatt machines. The capacity of its incandescent plant is now, therefore, 180 kilowatts, or about 2,200 lights.

The engines used to drive these dynamos are of the Green automatic type, slow speed engines, belted directly to the dynamos so that there are no countershafts, as shown in the accompanying engraving. The belts from the dynamos run off this slow speed shafting by means of very large pulleys, the diameter of which is about 12 feet. This extreme diameter renders it necessary to have long belt centres, and these vary from 22 to 26 feet. Link belts are used exclusively. The leads from the dynamos are brought overhead to the switchboard, bare copper rod supported on porcelain insulators being used throughout.

As the dynamos are of the compound-wound type there are three wires from each dynamo to the switchboard, and in order that either one of the dynamos may be used on either side of the three-wire system a special switchboard has been devised by the Edison Company and shown in the cut. It is practically a double-throw three-blade switch with a cross-connection between the upper centre and the right-hand lower clip. Connections are made to these switches in such a way that when the handles are all up the dynamos are all connected on the positive side of the system, and when the handles are down, the dynamos are all on the negative side. When two handles are up and two down, two dynamos are on each side of the system. Five feeders run from the switchboard. Each of the outside wires of the feeders is provided with a switch with a safety fuse attachment, the neutral of each feeder having a simple safety catch holder with fuse. On each side of the main switchboard is another smaller one on which are mounted the pressure indicator and galvanometers.

The pole line is about four miles long and there are about 21 miles of wire in the system. The line has a capacity of 1,500 lights burning at one time, and the idea at first was to wire the buildings for about 1,000 lights. Before the installation was complete, however, the demand for lights suddenly increased and the total number of lights connected at the time the station was started was about 2,000 16 c. p. lamps.

The energy displayed in the erection and completion of this plant shows the appreciation by the Peninsula Company of the fact that there existed an urgent demand for electricity in this rapidly growing town, and a desire to satisfy it without delay with as good a plant as could be obtained.

THE LAUNCH "ELECTRA."

In our last issue we gave a brief account of the new electric launch "Electra" and this week we are enabled to present several views of her. The engraving Fig. 1, shows her as she appeared on the Passaic River and Fig. 2 is a view looking towards the bow.

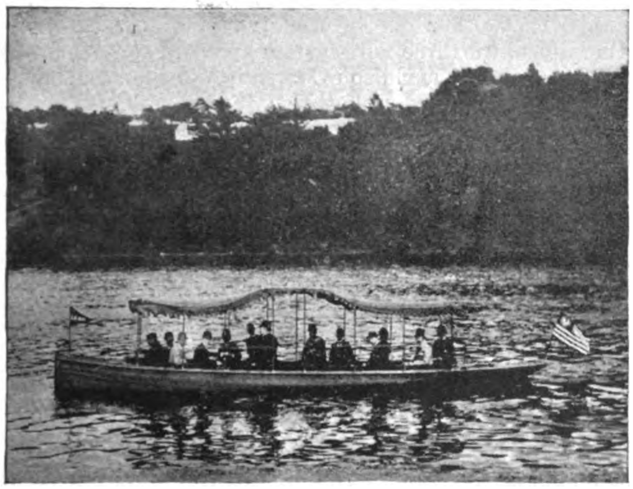


Fig. 1.—The "Electra."

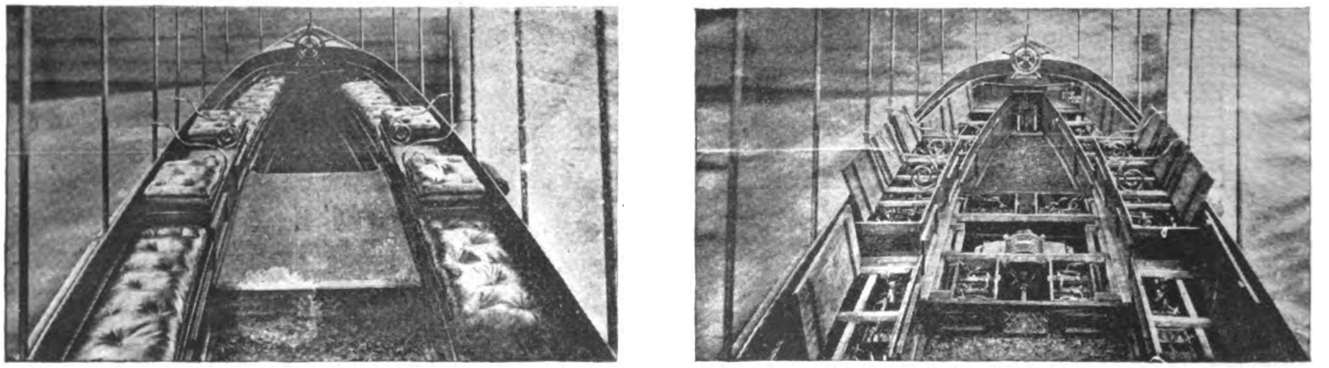
The arrangement of the cells and motor are well shown in Fig. 3 which is taken from the same point of view as Fig. 2. The "Electra" was built by the Electric Launch and Navigation Co., of this city, and is intended as a sample boat for the passenger traffic on the enclosed waters, at the World's Columbian Exposition, Chicago. She is to be submitted for test and approval by the Exposition management, and has already been shipped to Chicago with that end in view. This passenger traffic is expected to require some 50 or more such boats.

The dimensions of the "Electra" are as follows:



Figs. 2 and 3.—View Toward Bow; Showing Arrangement of Batteries and Motor.

Length, over all, 34 feet; length (loaded water line), 31½ feet; beam, 6 feet; maximum draft, 26 inches. She will seat from 25 to 30 passengers. Her motive power consists of 78 storage cells of the Consolidated Electric Storage Co.'s 17 S type, and a 4 h. p. Reckenzaun motor capable of developing as high as 12 h. p. for a stretch. She is fitted with an electrical whistle or trumpet and with electric incandescent lamps for signal lights and illumination.

The Wightman Electric Manufacturing Company, of Scranton, Pa., has its contract for the furnishing of twenty car equipments and a 300 h. p. generator for the Seashore Electric Railway Company, at Asbury Park, N. J., well under way.

ELECTRO-TECHNICAL EDUCATION.[1]

BY PROF. R. B. OWENS.

Until within the past few years the value of the manual element in education has been sadly overlooked in elementary instruction in this country. Special and distinct schools, called variously Manual Training Schools, Schools of Mechanic Art and Developing Schools, have arisen where those elements which underlie all industrial pursuits have been introduced into general elementary education, not because students leaving such schools expect always to enter upon some trade or into some "Trade School," but because such instruction is eminently "desirable for the roundness and unity of general education, and valuable no matter what the future of those so educated may be."[2] The Massachusetts Institute of Technology, the Washington University, St. Louis, and others, have attached to themselves schools of mechanic arts and manual training schools for the reason, I take it, that the elementary public schools do not afford such instruction, and they recognize the great educational value of their training.

In studying the various courses given in the best technical schools in this country and abroad, and the opinions of educators and engineers, I take it that a technical school is primarily a place for the preparation of men who expect to earn their living as engineers. It is not a school of general culture, nor is it a school of abstract science. It is a device to save time, and teaches the applications of pure science to industrial purposes.

A technical school is also, I claim, a post-graduate school in the ordinary sense, and in this respect should rank with schools of law and medicine. If the engineer is a man who uses both the results of science teaching and mechanical skill, he must certainly have great familiarity with both, and the attaining of such familiarity will constitute his undergraduate work. But, after such general knowledge is acquired, no time should be lost in fitting each student to be of the greatest immediate value to those who employ him. Unfortunate as it may be, we must reconcile ourselves to the necessity of becoming specialists. It may be argued that "The more a man knew of all the related branches the better he could perform his special work, but this is only arguing the advantage of omniscience."[3] Time was when all known about electricity would not greatly tax the ordinary intellect, but now each student can only hope to become an expert in one very narrow department, and I believe we must shape the courses, as far as possible, in our electro-technical schools to meet the requirements of the times.

Of course, to employ a number of specialists and to give each student the opportunity to choose the work he is best fitted for will be expensive, but if our country is to keep pace with others in industrial progress she must educate her engineers. When private generosity fails, State aid must be forthcoming or we will have to witness others surpass us in the race for international position. "It is in consequence" of superior industrial and technical education "that Germany is gaining a better industrial position daily."[4] And the same might be said of several other foreign countries, so that on the score of economy no more profitable expenditure of public money is possible than for the support of technical schools. Education is not a money-making business. "No fact is more firmly established all over the world than that higher education can never be made to pay for itself."[5] No considerable income can be anticipated from student fees. Higher education must look for its support to private munificence or public help, and, as suggested to the English Institution of Electrical Engineers by Prof. Ayrton, it would seem to be the duty of such a body as this to influence as far as possible public opinion in favor of advanced electro-technical education.

[2] President J. D. Runkle, "Manual Element in Education."

[3] T. M. Drown, *Journal Franklin Institute*.

[4] Prof. R. H. Thurston.

[5] Prof. Rowland.

Having seen the importance of manual training as a factor in elementary education, and knowing its special value to those intending to become either handicraftsmen or engineers, I would recommend that a fair knowledge of forging and foundry work, pattern making, wood and metal turning, and drawing be required of every student for matriculation into any college course. Such an elementary knowledge can readily be acquired by the average student by the age of 16 or 17, along with the elements of English education, such as given in our high schools and academies.

The importance of drawing can hardly be overestimated. It is rightly called "the shorthand language of modern science," and every one can learn to draw with a fair degree of accuracy, although the "negative faculty of drawing in some people is almost miraculous."[6] I do not mean artistic drawing, painting and perspective, but the elements of orthogonal projection can be as easily acquired as the art of writing, and for some purposes it is just as useful. At the age of 16 or 17 a boy having had good advantages should be able to enter any of our best American colleges, and here, if he intends becoming an electrical engineer, I would have him study for three years mathematics, chemistry and physics, with German and French. These apparently few subjects will absorb the greater portion of his energy. Nothing is gained by working at excessive pressure in early life; and as to knowing anything about engineering itself, it would seem best to leave that alone until a thoroughly good scientific education had been first acquired. When electrical engineering is taken up in earnest the student should have such a command of physical and chemical facts and methods, and be such a master of mathematical analysis as to leave him free to discuss engineering problems without the necessity of first acquiring the facts and methods he may wish to make use of.

A good course in modern geometry, differential and integral calculus, say, according to Williamson, and differential equations, say, Forsyth or Craig, would be sufficient to pursue with advantage nearly any course in electrical engineering given in this country at the present time, and when in reading Maxwell it becomes convenient to have quaternions or spherical harmonics, they can be studied in connection with such reading. But to attempt to analyze the action of alternating current apparatus without the use of differential equations, is, to say the least of it, no very easy task. We admit the value of geometrical methods and especially as expressing in convenient form, the result of algebraic analysis. Indeed, in the hands of Mr. Kapp, Mr. Blakesley and a few others, they have been used with excellent analytic effect, but their general weakness as compared with modern methods, is too well known to need comment. As regards the amount of general physics required, I should say the student ought to be familiar with the theory of heat measurements, thermo-dynamics, the principles of fluid motion, the dynamics of a particle, and of solid and rigid bodies, the theory of sound and physical optics, and the facts and principles of magnetic and electric actions. Above all he should be able to apply mathematical reasoning to physical problems and be skilled in the art of experiment.

In ordinary electrical work a knowledge of inorganic chemistry would perhaps suffice, but if one expects to make a specialty of electro-chemistry, then both organic and inorganic chemistry should be required.

Besides mathematics, chemistry and physics, which must be considered as principal subjects of the directly preparatory course, German and French should be acquired, as so large a part of our best electrical literature is in these languages. Sanscrit and psychology might be classed as electives, as affording variety.

Assuming that a thorough working knowledge of mathematics, physics and chemistry is possessed by the student, then I believe he should spend three years in studying the applications of his acquired facts and principles before attempting to practice his profession.

We must, I think, recognize three classes of electrical engineers in this country at this time: First, the installing engineer, who superintends the equipment of central or isolated electric light or power plants, electric railways, mining plants, etc., and runs them when completed. In this class of work more than a knowledge of electricity is required. It becomes essential to have a thorough knowledge of steam engineering, track and pole line construction as well. He should be as well able to choose the best engine and boiler for a given set of conditions, and to install and operate them economically, as he is able to choose the best dynamo, motor, line wire or lightning arrester. A practical knowledge of building foundations, laying out railway curves, and running pole lines, is to this engineer a matter of greatest importance.

The next distinct class of electrical engineers I would recognize, are designing engineers, who rather have to do with the manufacture of electric apparatus, than its installation. Such men design and superintend the construction of the apparatus put on the market by the several manufacturing firms, but rarely also have to do with steam engines, track construction, or pole lines. To this second class, a correct knowledge of machine design is of equal importance with a knowledge of magnetism and electricity, and it was perhaps of such men that Lord Kelvin was thinking when he said an electrical engineer should be nine-tenths mechanical and one-tenth electrical.

The third class of engineers are employed by standardizing bureaus, and in laboratories, to make tests of electric and magnetic constants, calibrate, instruments, etc. For such work neither a knowledge of pole lines, foundations, or machine design, is so important as familiarity with delicate methods of measurement and skill in manipulating sensitive instruments. It would seem best then to shape the course in any electro-technical school, as far as possible, to meet the requirements of these distinct classes of engineers.

The proportions of the three kinds I have named vary greatly in different parts of the country. To meet the immediate home demand for engineers, I believe our Western schools of engineering must make a specialty of training installing engineers. In the East the case is different. More men are employed by manufacturing firms, testing and standardizing bureaus, than by construction and engineering companies, so that the course given in the Eastern schools of engineering, and which are largely for the designing engineer, are justified.

A synopsis was then given of the course of instruction in electrical engineering at the University of Nebraska, the electrical equipment of which was declared by Prof. Thurston some months ago to be the finest, considering its size, in the United States, and the author closed as follows:

No attempt has as yet been made to teach telegraphy practically, and as we have here some members who have had much experience in practical telegraphy, I hope they will express their opinions as to the advisability of introducing it into electro-technical schools. Some declare it properly belongs to engineering, and others contend, with much truth, I think, that it properly belongs to a trade school. Similarly with wiring, electroplating and electrotyping. Is a practical knowledge and skill in them to be gotten in or out of the school?

THE TECHNICAL EDUCATION OF THE ELECTRICAL ENGINEER.[1]

BY PROF. DUGALD C. JACKSON.

PERHAPS it would be well to call my subject the "College Education of the Electrical Engineer," for it is strictly of the technical college course that I shall speak. We can truly affirm that the technical education of an engineer does not end until his work is ended, and the college course is but the commencement of it. It is neither possible nor desirable that the courses of study of electrical engineering students in the various schools should be alike, but a certain unity of purpose and treatment should be observed, and all can profit by the suggestions made by the practical man. With this in view, I present the subject to your attention as it is looked upon at the Engineering School of the University of Wisconsin. There is no originality claimed for the ideas presented, as they are based upon the recorded experience of some of the country's most successful practical men, and are virtually followed in such other engineering schools as make their courses thoroughly practical, and therefore, in the true sense, professional.

In order to enter the freshman class of the best engineering schools, the applicant must have a thorough common school education, including mathematics through ordinary algebra, a fair knowledge of English, a reading acquaintance with German or French, a little elementary physics and chemistry. In order that an engineer may use his abilities and training most advantageously, he should have a good general education, including a fair knowledge of literature, history, economics and certain elements of law. To have an average chance of proving successful, an electrical engineer must be well grounded in three sciences besides those gained in the common schools, and which cannot be classed as engineering. These are: Higher mathematics, as far as it may be practically applied in engineering; chemistry and physics (including elementary electricity and magnetism).

At the University of Wisconsin, during the first year the student is given a course of four subjects, continuing through the year. These are: 1st, English and rhetoric, with such reference to technical forms as seems desirable so early in the course; 2d, mathematics, beginning with higher algebra, passing through trigonometry and descriptive geometry, and into analytical geometry; 3d, advanced French or German, grammar and reader; 4th, manual training. In the latter, which continues during the following two years, we do not think it necessary or desirable for the student to spend sufficient time during his course to become a carpenter, machinist, blacksmith or foundryman. His future calling will probably not demand that his wages be earned in any of these trades; but they are tributary to his profession, and he must have an intelligent mastery of the tools. and an appreciation of shop requirements. Mathematics are also continued through the second and third year, during which time analytical geometry, calculus and applied mechanics are passed through. All mathematics are taught with special view to future *practical* applications, and good use is made of the laboratory in applied mechanics. During the second year of the course, elementary chemistry and physics are disposed of, and here again the laboratory is put to good service. At the same time, work in draughting and the elementary designs of machines is begun. The third year is about half, and the fourth year wholly, devoted to what may properly be called professional studies.

---

[6] Prof. Huxley.

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 7, 1892.

It may here be asked, Of what use is the severely specialized education to the successful student in the engineering courses? The graduate does not become an engineer merely because he has successfully met the college examination. College cannot make an engineer, however practical the course of study may be. Practice has made thousands of good ones without the aid of the college, but I venture to say that these would frequently have become more eminent if they had received a thorough technical college course. While theory alone, wherever learned, cannot make a practical man, it is the one who can follow the guide of theory along the paths of practical work and experience, who makes the fully developed engineer. In order, however, that neither theory nor practice may lead him astray, he must have a *well-educated common sense.*

The true object of the technical college is to teach the fundamental theories, with a common sense view to their practical applications, in such a way as to aid in a diagnosis, not by the application of a mathematical formula, but by comparing the accumulated experience of the practical world. Take two young men of equally *good* ability and equal age; put one through a thorough technical college course and the other through an apprenticeship of the same length of time. Finally, put them side by side in a working position, where they must work out their own salvation, and the college man will usually have more ambition and adaptability, and will outstrip his mate, though perhaps not at once. The college man may fall behind at first, but, having worked through the transition period, he will prove the winner. I venture to say this is the well-nigh universal experience of those who have had the opportunity of dispassionately trying the experiment.

It is comparatively easy to properly teach the fundamental theories; hence it is so frequently overdone. It is not so easy to educate the judgment of a student in electrical engineering, whose entire knowledge of his future profession has been acquired from the electric bells in his father's house, and who may never have examined a dynamo or storage battery until he visited the college laboratories. But it is wonderful how rapidly such students, when of good timber, absorb a beginner's information and a thirst for investigation. In this part of the student's education, the manufacturers and large users of electrical apparatus, who have become directly or indirectly interested in the work of the graduates, can assist with little direct inconvenience and much indirect advantage. In a properly organized technical school, as shown above, the student gains his fundamental theory during the first three years, and, if of good timber, he will absorb much of the practical methods of thought required for successful afterwork. Moreover, a considerable part of the third year is spent in practical instruction. As the fourth year is wholly spent in practical training; or the education of the common sense, the student must have some acquaintance with the methods of commercial work before entering it, in order that he may properly profit by the instruction. It is impossible for many, and doubtless undesirable for the majority, to take a year from the midst of their college course for outside work. The summer vacation between the third and fourth year should, therefore, be occupied in some such employment as wireman on electric light or telephone construction, or better, in the station and repair-room of an electric railway, under the eye of an appreciative superintendent. Three months spent in this work may seem very little, but it will do a deal of good in giving an apt student a fair idea of how far exact formulas will carry him. It is only by the generous co-operation of employers, that students can obtain this summer's work. At first thought it appears that the employer gains no advantage from it, but upon careful consideration, an advantage is evident. To begin with, the properly trained student will not prove useless during the summer, and the satisfactory one will usually find employment after graduation, with the interests of those who afforded him summer work, and who thus gain the benefit of his greater advancement during his last year at college. In a similar manner, the manufacturer gains an advantage from placing his apparatus in the technical school laboratories for *proper* use in instruction.

We can now usefully inquire into the specialized work that should be prescribed for the average electrical engineering student during his last two years at college. Up to this point, students in mechanical and electrical engineering courses have received virtually the same instruction. Here, we hold, with several others, their paths should diverge. The student of mechanical engineering goes into careful study of shop practice, designing and utilizing various types of machinery, and similar subjects. The electrical engineering student must receive a good working knowledge of the problems of the mechanical engineer, but he must above all be trained in the practical problems of electrical engineering. He, therefore, goes into a study of that which will aid most in making him truly an electrical engineer. His knowledge must all be based on mechanical laws, but he must be much more than one-tenth electrical.

Before reaching his truly professional studies, the student should gain, during his course in physics, a common sense grasp of the elementary notions of electricity and magnetism, and of the "all-pervading law of Ohm." The latter can be properly enforced in the laboratory by placing in the student's hands ordinary electrical instruments, such as bridges, galvanometers, amperemeters, voltmeters, etc. Before beginning his specialized work, the student's knowledge of Ohm's law and its common results should have become almost instinctive.

With due regard for his preparation, it seems best to arrange the professional studies for the average electrical engineering student in four divisions, thus:

1st. Electromagnetism and its application to practical uses, with special reference to dynamos and motors.

2d. Electro-chemistry (including primary and secondary batteries) and electro-metallurgy.

3d. Alternating currents and alternating current machinery, including dynamos, converters, condensers, etc.

4th. The special application of the preceding divisions in electric light, power, railway, mining and other types of plants.

The last division is allotted about twice the amount of time given to each of the others.

While higher mathematics is a useful aid in each of the divisions, its limitations as an agent must be carefully set forth in the class-room and laboratory. For the purpose of educating the judgment and fully defining the limitations of theories and mathematical deductions, the laboratory is indispensable. As much as one-half of the total time spent by the student under the direct instruction of the professors of electrical engineering, should be devoted to the laboratory. This work, moreover, should, as far as possible, deal with commercial instruments and machinery, and actually follow the methods of testing and research used in practice. Physics, chemistry, mechanics, steam engine, hydraulics, dynamos, electrolysis, alternating currents, and other subjects, should all be properly represented by a commercial laboratory equipment, which is made useful in every-day instruction under the direction of a man who has had experience in similar commercial work.

The student who satisfactorily completes a *proper* professional course at college, whether laid down in the college catalogue or carefully elected from that prescribed, is not likely to become one who "turns out results like a cornsheller, and never grows wiser or better, tho' it grinds a thousand bushels of them."

PRACTICAL NOTES ON THE ELECTROLYTIC REFINING OF COPPER.[1]

BY F. B. BADT.

It is the object of this paper to give a few practical data in relation to American practice, and to give a short description of the processes in vogue in this country. While the writer has erected some of the largest copper refineries in the United States, and examined a few of the other plants, the data which the writer submits in the following are not claimed to be either complete or to be absolutely correct. The writer has endeavored to tabulate the electrolytic copper refineries in the United States.

In the following we give a list of electrolytic copper refineries in the United States. It shows us that there are at present 36 dynamos of a total capacity of 1,814 kilowatts used for the electrolytic refining of copper, and that the total output of these refineries (when all are completed) will amount to 3,650 tons per month, or 43,800 tons per year. A capital of over $1,000,000 is invested in these refineries.

The Census Report, dated Washington, D. C., July 15, 1891, shows the United States to be the largest producer of copper in the world, its product for the year 1889 being 226,055,962 pounds, or 113,028 (short) tons. The total expenditures involved in this production were $12,062,180, of which there was paid in wages, $6,096,025; in salaries, $120,896; to contractors, $334,443; for materials and supplies, $4,067,970; and for taxes, rent, etc., $1,442,846, the total capital invested being $62,623,228, and the total number of employees, exclusive of office force, 8,721. The same Census Report gives some statistics on "copper refining," but unfortunately fails to state how much copper was refined by the electrolytic process.

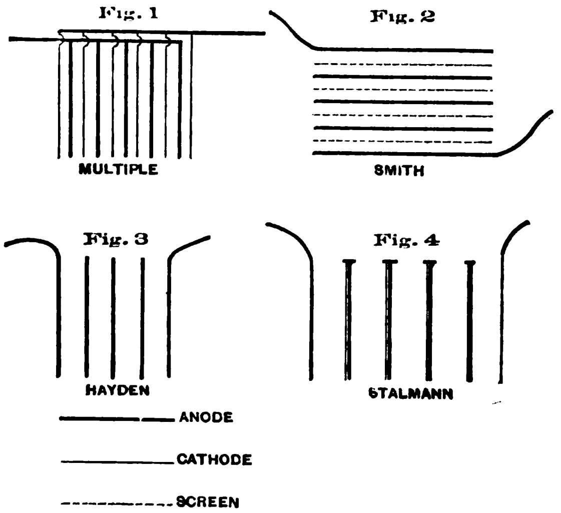
The returns cover establishments which produced 159,693,252 pounds (79,847 tons) of refined copper, valued at $19,686,561.86.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 6, 7 and 8, 1892.

Hence if our list is approximately correct only about 25,000 tons out of 79,847 tons of refined copper were treated electrolytically.

In the table below, I mention, in the fourth column, the names of certain processes in vogue in the United States, and it might be well to show the main features of each. The crude material used in the anodes is black copper, or blister copper, containing from 97 per cent. to 98 per cent. of copper. The electrolyte is a solution of sulphate of copper. In some processes refined copper is a by-product only, especially when it appears in a concentrated form in the mattes of lead smelters and refiners. In the process which we call the "multiple process," anodes and cathodes in each vat are arranged in multiple, in about the same manner as the plates in a storage cell. (See Fig. 1.) In this process there is usually one more cathode than there are anodes. The electrodes are suspended in a vertical position in wooden vats usually lined with lead. The vats themselves may be arranged either in series, in multiple, or in multiple series. For simplicity's sake and for numerous other reasons well known to the electrical engineer, an arrangement of vats in single series is most advantageous.



METHODS OF COPPER REFINING.

Another process is the "Smith process" (United States patent No. 393,526, Nov. 27, 1888.) In this process there are no cathodes of pure copper. The plates of black copper (anodes) are not suspended vertically in the solution, but are placed horizontally. As it would not be practical in many places to cast the plates large enough to give a sufficient amount of surface, several plates are placed side by side so as to form one large plate. These layers are then placed one above the other at a distance of about 1½ inches, the layers being supported by strips of wood running lengthwise of the vat. The top plate is connected as an anode to the generator, and the other pole of the dynamo with the bottom plate. The spaces between the plates are filled with the solution of sulphate of copper, which forms the only connection between the plates. The copper is dissolved from the under surface of each layer and deposited on the upper surface of the next layer below. The insoluble foreign matters in the copper, including gold and silver, fall upon screens of cotton cloth which are stretched between each two layers. The process is kept up until all the black copper is dissolved and nothing remains but plates of electrolytic copper. Fig. 2 shows the relative position of plates in one vat. The inventor claims several important advantages over the common vertical multiple arrangement. He claims that the silver or other foreign insoluble matter is removed, that the space required for a given amount of depositing and the amount of solution required are relatively small, that the connection between the plates in one tank is made by the solution only and that the copper is easily handled and prepared for the vats. Smith arranges all vats in series.

Another process mentioned in the list is the "Hayden" (Fig. 3, United States patent No. 465,525, Dec. 22, 1891). The Hayden process differs materially from that of the Smith only in that he places his plates in vertical position instead of placing them horizontally, and that he does not use any screens. Hayden also arranges his vats in series.

LIST OF ELECTROLYTIC COPPER REFINERIES IN THE UNITED STATES.

Name of company.	Generators.	Number of of vats.	Process (arrangement of vats).	Output in electrolytic copper per month, tons.	Remarks.
1. Anaconda Mining Company, Anaconda, Mont.	5 Edison—60 volts, 1,100 amperes.	320	Partly multiple, partly Stalmann.	350	Plant being extended for ultimate capacity of 900 tons per month.
2. American Nickel Works (Jos. Wharton), Camden, N. J.	1 Excelsior—6 volts, 1,000 amperes.	48 in series.	Multiple..................	30*	By-product.
3. Balbach Smelting and Refining Company, Newark, N. J.	7 Excelsior—15 volts, 2,000 amperes. 1 Excelsior—30 volts, 3,000 amperes.	7 series of 48, 1 series of 96	Multiple (18 anodes, 81 cathodes).	650	They refine the product of the Oxford Copper Co., whose smelters are in New Jersey, and who are general purchasers of copper ores, matte and bullion.
4. Baltimore Copper Smelting and Rolling Company, Baltimore, Md.	6 Edison*—150 volts, 400 amperes.	....	Hayden...................	800	Generators have sectional fields which can be plugged for different voltages.
5. Baltimore Refining Company. Baltimore, Md.	2 Edison—80 volts, 700 amperes.	....	Hayden...................	300	
6. Boston & Montana Consolidated Copper and Silver Mining Company, Great Falls, Mont.	3 Thomson-Houston, multipolar separately excited, 165 volts, 1,000 amperes.	288	Multiple (19 anodes, 19 cathodes).	550	Plant in construction. Dynamo capacity in excess of present requirements.
7. Bridgeport Copper Company, Bridgeport, Conn.	1 Thomson-Houston, 1 Mather, 1 Edison—150 volts, 400 amperes.	3 series of 10	Hayden (100 electrodes in each vat).	400*	They refine the entire product (black copper) of the Parrott Silver and Copper Company, Butte, Mont.
8. Chicago Copper Refining Company, Blue Island, Ill.	2 Edison—80 volts, 800 amperes.	165	Multiple................	150	
9. Electrolytic Copper Company, Ansonia, Conn.	3 Mather—100 volts, 300 amperes	75	Smith....................	100	
10. Lewissohn Bros.† Pawtucket, R. I.	1 Excelsior—15 volts, 2,200 amperes.	60 in series.	Multiple (19 anodes, 19 cathodes).	110	
11. Omaha & Grant Smelting Works, Omaha, Neb.	1 Excelsior—6 volts, 1,000 amperes.	48 in series.	Multiple..................	30	
12. Pennsylvania Salt Manufacturing Company, Philadelphia, Pa.	....	....	Smith....................	30*	By-product.
13. St. Louis Smelting and Refining Company, Cheltenham, St. Louis, Mo.	1 Excelsior—16 volts, 2,400 amperes.	48 in series.	Multiple....	60*	This plant is operated in connection with an electrolytic silver refinery, using the Moebius process.
14. Washburn, Moen & Co., Worcester, Mass.	....	....	....	90	Plant burnt, being erected.

† Agents for the following mining companies: Boston & Montana Consolidated Copper and Silver Mining Company, Montana; Butte & Boston Mining Company, Montana; Arizona Copper Company, Arizona; Huron Copper Mining Company, Lake Superior. Mich.; Tamarack Mining Company, Lake Superior, Mich.; Osceola Mining Company, Lake Superior, Mich.; Kearsarge Mining Company, Lake Superior, Mich.; Santa Fé Copper Company, New Mexico; Peninsula Copper Mining Company, Lake Superior, Mich.

Another inventor, Stalmann (United States patent No. 467,350, Jan. 19, 1892, and No. 467,484, Jan. 19, 1892), practically uses the same process as Hayden, only, instead of using single plates he uses, with the exception of the initial anode and the terminal cathode, pairs of plates of crude and refined material, but brings the two plates together by connecting them by one or more bolts or rivets so that they become practically a pair of anode and cathode plates with no electrolytic solution between them (Fig. 4).

One pound of copper will be deposited in one hour theoretically, by a little less than 386 amperes out of a solution of sulphate of copper. If we, therefore, pass 386 amperes through one vat, we will deposit one pound every hour and if we pass the same current through a series of 100 vats, we will deposit 100 pounds each hour. The amount of power expended in each vat, however, is $C^2 \times R$, but as it is always possible to reduce the resistance of a vat by increasing the surface of the plates, we can greatly reduce the amount of power required for the same output in copper per horse power hour. We may also reduce the ampereage for a given production by joining more vats in series, or we may combine both methods.

It is therefore always possible to largely reduce the expenditure of electrical energy, and consequently that of the motive power. As a matter of fact, theoretically, any amount of copper may be refined with any given horse power, but as soon as we attempt to largely increase the production of copper with a given power, we find it necessary to largely increase the size and number of vats and the quantity of copper under treatment. These conditions have been thoroughly examined, and the laws governing them have been explained in the several hand-books extant.

Another important item in order to obtain a pure deposit is the density of the current. American copper refiners usually adopt 10 amperes per square foot of active cathode surface as a maximum. I am told, however, that some of the refineries operating on the "Series" processes go even beyond 15 amperes per square foot, which may account for certain impurities found in the electrolytic copper and for a greater efficiency of the plant; that is, a larger output of copper for a given number of vats and amount of copper under treatment.

High voltage in an electrolytic plant of course means considerable saving or less drop in conductors, less trouble from poor contacts, etc., and it is probable that for these reasons the so-called series processes show a greater efficiency per given horse power than the processes employing electrodes in multiple.

Another important item for the obtaining of pure deposits is a good circulation of the electrolyte. This insures a uniform specific resistance in the solution between the parts of the plates.

In American practice, the electrolyte is sometimes kept in circulation by arranging the tanks on the cascade plan, and have each higher vat siphon through a pipe whose orifice is near the bottom of the next lower vat. A better plan now usually adopted is to have a trough run through the whole refinery, and have each vat fed independently by means of a rubber hose. The electrolyte is raised from the collecting tank into the troughs by means of lead pumps or steam injectors. Both, however, are objectionable. The pumps are always getting out of order, and the steam injector means waste of steam, besides having the disadvantage of putting too much moisture into the electrolyte, which again necessitates the adding of free acid continually. A better plan is to have two collecting tanks, which are to be used alternately. Just as soon as one is full it is made air-tight, and a small air compressor driven by an electric motor compresses the air above the solution and drives the solution under a pressure of, say, 25 pounds through a pipe up into the troughs. Smith claims that in his arrangement no artificial circulation of the electrolyte is required.

We might mention another incidental advantage of the multiple process over the series processes. Some of the patentees claim one-fourth of a cent per pound of refined copper as a royalty. In one instance one plant gives the patentee, under this arrangement, an income of over $100 per day. Taking this in combination with the very doubtful advantages claimed for the series process, we need not wonder that there exists prejudice against erecting electrolytic refineries employing these patented operations.

I could enumerate a long list of defects that exist to-day in almost all of the electrolytic refineries, and which may all be traced to one cause, and that is, the imperfect knowledge of the refiners, of matters electrical. As a matter of fact, all the experiences which we have gone through for the last ten years in constructing electric light and power plants, have been of no benefit, it seems, to most electrolytic refiners. Even in the few installations where a voltmeter is used to indicate the proper working condition of the vats. this voltmeter is carried by two men from vat to vat, and the voltage of each vat is taken in this cumbersome manner.

In a plant just being erected, the writer proposes the erection of a potential board in the office of the superintendent. Both terminals of each vat are to be connected with two contact points of the potential board, and a voltmeter is to be so arranged that by simply turning a switch handle the potential of each vat can be taken almost instantaneously. One of the occurrences which has to be guarded against is the short-circuiting of an anode and a cathode, which in the multiple plan means the short-circuiting of a whole vat. Such an occurrence should be detected immediately, as otherwise the contents of the vat may be spoiled. The author proposed for a plant just being erected an electric tell-tale in connection with the potential board.

Some of the electrolytic refineries in the United States buy copper matte of from 45 to 54 per cent. of copper from the mining companies. In these cases they own their own smelters, resmelt the copper matte, producing black copper of from 97 to 98 per cent. of copper. This black copper is then cast into anodes and subjected to the electrolytic process. Other refineries buy the black copper direct from the smelters owned by the mining companies. For instance, the Bridgeport Copper Company, of Bridgeport, Conn., buys the entire product of the Parrott Silver and Copper Company, of Butte, Mont., as black copper.

There is another matter which should be mentioned, as it is very often misunderstood by the public and the electric companies. If copper matte contains, according to the assay, 30 ounces of silver or less per ton of matte, no extra charge is made for the silver, but the copper matte is sold at the reigning market price. If it contains, however, over 30 ounces, the silver is to be paid in accordance with the assay. Thirty ounces of silver per ton of matte, of course, means almost double that amount per ton of electrolytic copper. It can easily be seen that electrolytic refineries prefer to buy copper matte containing just a trifle less than 30 ounces of silver per ton.

There are quite a number of points which need the attention of electrolytic copper refiners. There are, for instance, only a few of the refineries which manufacture their own sulphate of copper, but buy it at high rates in the market. Sometimes the cost of freight and haulage doubles its cost. Each copper refinery should have a little installation of its own for the manufacturing of the necessary sulphate of copper, which it can do at a small fraction of what it has to pay for it. The same holds good in relation to the refining of the slime or mud which collects at the bottom of the vats, and which contains the precious metals. Each copper refinery should have its own little plant for the refining of the mud. These little installations can be run at a small expense in connection with copper refineries, and it is almost nonsensical to have other concerns make large sums of money which could be saved by the refiner himself.

A few words as to electric generators may not be out of place. The author prefers separately excited machines for the reason that they cannot be reversed and for other incidental advantages. When water-power is used as prime mover a good deal of trouble has been experienced in the regulation of the wheels. As a matter of fact there is no water governor in existence which will regulate so perfectly as the governor of a modern automatic engine under varying loads. By running all the exciters from an independent prime mover (either water or steam) the strength of the fields of the generators will be uniform at all times whether there are fluctuations in the external circuit or not; the strength of the field of the generators which, with self-exciting machines, is subject to the fluctuations in the external circuit, and is a variable, becomes a constant. The author proposed this arrangement over three years ago for railway and power stations with the very best results.

There are other processes which contemplate the extraction of copper direct from the ores by means of electrolysis. The best known are the "Siemens" and "Hoepfner." If we are correctly informed the Siemens process is now being used in one experimental plant only, which is used by the Siemens firm. This is at Martinicken Fields, near Berlin. Dr. Hoepfner's process, it is claimed, is now in operation in three plants; one at Schwarzenberg, which began operations in September, 1890, and two others about which very little has been published. Dr. Hoepfner uses in his process a cuprous chloride solution, out of which a current of one ampere will deposit 2.35 grammes per hour, while out of a solution of sulphate of copper, only one-half of this amount of copper can be deposited per unit of current per hour.

We finally give below the approximate cost of a refinery with a capacity of 1,000,000 pounds of electrolytic copper per month:

Building	$30,000
Pavement (asphalt)	2,000
Pipes for steam heating	4,000
Vats	6,000
Lead for lining vats, collecting tanks and troughs	28,000
Lead burning	1,500
Copper conductors	11,000
Rails for overhead blocks for handling plates	2,000
Sulphate of copper	3,500
Sulphuric acid	1,000
Steam injectors or pumps or air compressors	1,000
Electric generators, switchboard, instruments	30,000
Shafting and belting	3,000
Total	$123,000

To this sum must be added the copper under treatment, which in this case will amount to at least $80,000, and, if a steam plant should be required, another $20,000 must be added, bringing the total of this plant up to $223,000. The above items include labor of erection, but do not include freights. These figures, although approximate and true only under certain conditions, will demonstrate that electrolytic copper refineries are expensive plants, and should be erected on carefully prepared plans and under the supervision of responsible and competent engineers.

THE WASHINGTON CONSTRUCTION CO. are installing a 200-light Edison plant at River View, one of the many Washington river resorts.

LONG-DISTANCE TRANSMISSION FOR LIGHTING AND POWER.[1]

BY CHARLES F. SCOTT.

A DESCRIPTION is here given of two plants, one for lighting and the other for the transmission of power. The conditions which have been met include a very considerable distance, extreme difficulties of climate and roughness of country, exacting requirements in continuity of service, and a pressure above that ordinarily used in the class of machines employed. The plants to be described are the first of their type installed in this country, and the apparatus in the power plant is of a kind that has not been heretofore used. The type and construction of the machines, and the arrangement of apparatus are new in many particulars, and as they have contributed largely to successful operation they will be described with some minuteness. Alternating current machinery is employed, constructed by the Westinghouse Electric and Manufacturing Company, the pioneer company in alternating work in this country.

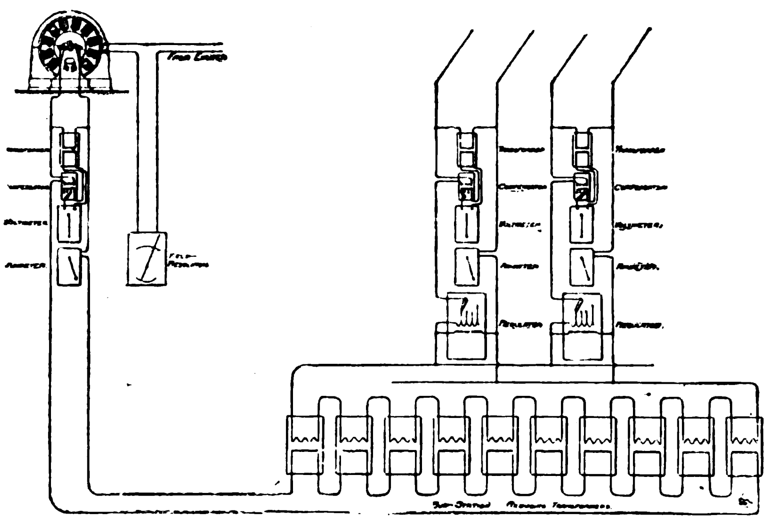


FIG. 1.

The lighting plant was first installed. It is operated by the Willamette Falls Electric Company, of Portland, Ore. The falls of the Willamette River at Oregon City, in the combined points of size, accessibility and nearness to the seaport, are unequaled. These falls, estimated at from 200,000 to 250,000 h. p., are about 13 miles from Portland, and it requires but a moment's thought to appreciate the value of an agent which can make this power available in the city.

The Willamette River is about one-quarter of a mile wide, and the fall is about 40 feet. The present station is located on an island at the middle of the river. Victor wheels of 300 h. p. are geared to horizontal shafts, from which the dynamo belts pass to an upper floor at an angle of 45 degrees. Two alternating current dynamos for incandescent lighting are driven by each wheel. The current, at a pressure of 4,000 volts, passes directly to the line of No. 4 B. and S. wire, which is carried on ordinary double-petticoat glass insulators across the level country to a sub-station in Portland. The current is received at 3,300 volts by transformers in the sub-station and is reduced to 1,100 volts for distribution by various circuits through the city to ordinary transformers, by which it is reduced to 50 or 100 volts. See Fig. 1.

When the apparatus was designed, it was not considered practicable to generate 4,000 volts with the ordinary type of machine, in which the wire is wound upon the surface of the armature, on account of the difficulty of insulating for more than 1,000 or 2,000 volts. The work was undertaken with a new type of armature, which is specially noteworthy, as it has rendered high potentials practicable in a machine of simple construction.

The field of the dynamo is of the ordinary type of alternating current machine in use in this country. The casting is circular in form, with 12 inwardly projecting poles of laminated iron, on which the field coils are placed.

The armature, Fig. 2, is built up of laminated discs, which are punched with 12 T-shaped teeth. The armature coils are wound in a lathe, are carefully taped and insulated, and are then placed over the teeth and sprung in under the projections. The space between adjacent coils is filled by a block of wood, which holds them in place securely. The field current is supplied from a direct current machine, and the main current is taken from two collecting rings on the armature shaft.

The reducing transformers are placed in a vault in the substation at the city. They are arranged in banks, or units of 10. Each bank is supplied by a separate dynamo, and has a capacity of 1,250 16 c. p. lights. The coils of the transformers are separately wound and taped, and are separated from one another and from the iron by strips of wood, Fig. 3. The primaries are connected in series for receiving 3,300 volts, and the secondaries are in series for delivering 1,100 volts, so that there are 330 volts in the primary, and 110 volts in the secondary of each converter. This method of connection throws small differences of potential in any single coil and permits the use of conductors of good size. The efficiency of the transformer at full load is 96 per cent.

The operation of the system is simple. The voltmeter or potential indicator is supplied by the secondary of a converter reducing in the ratio of 30 to 1. In the voltmeter circuit, Fig. 1, there is placed a compensator, which is a small transformer with its primary in series with the main circuit, and its secondary in series with the voltmeter circuit, and connected in such a way that the compensator pressure, which is proportional to the main current, is opposed to that of the converter. The compensator is so adjusted as to introduce into the voltmeter circuit a counter E. M. F. proportional to the loss in the conductors, so that the voltmeter indicates the potential at the distant end of the line. The compensator effects the same result as pressure wires run from the point of supply back to the station. The E. M. F. at the dynamo is adjusted for each load by regulating the field current so that the voltmeter shows the proper indication, thus keeping the pressure at the sub-station constant at 3,300 volts. The pressure at the dynamo is slightly in excess of this at light loads, and is increased to 4,000 volts at full load, to cover the loss of transmission. The secondary current from the reducing transformers is treated as if it were received directly from a dynamo. On each supply circuit from the station there is a voltmeter with a compensator set for the loss in this circuit. The exact adjustment of E. M. F. on a circuit is made by a regulator, consisting of a transformer with its primary connected directly across the main terminals, and a secondary divided into small sections, each having an E. M. F. equal to one per cent. of the primary. Any number of these sections may be placed in series with the supply circuit, thus varying the E. M. F. at will. This form of regulator

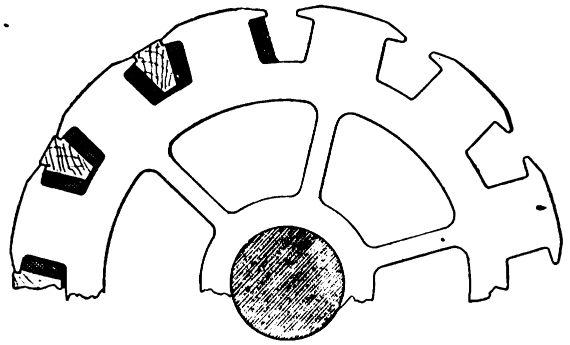

FIG. 2.

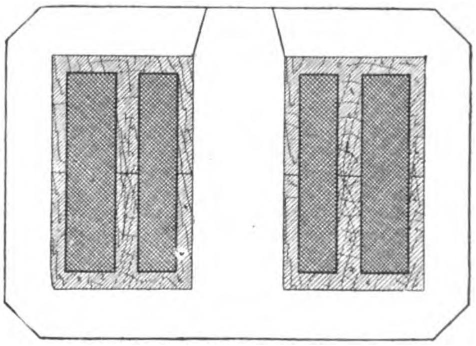

FIG. 3.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, Ill., June 6, 7 and 8, 1892.

is of high efficiency, as it converts but a small percentage of the total energy, and the loss is a small fraction of this percentage.

The plant was first installed with two incandescent machines and started nearly two years ago. Since that time, five additional machines have been added, so that there are now seven, each with a capacity for supplying 1,250 16 c. p. lights, in Portland. The total capacity is 8,750 lights. The dynamos run admirably. One explanation of the success of the plant is the intelligent policy of the general manager, in harmony with his statement that, "It is not the first cost which counts, but the cost of throwing out and replacing apparatus."

The same policy has happily governed the installation of the second plant to be described—the power plant. This is located near Telluride, Col., and is owned by Mr. L. L. Nunn. The Gold King mill requires power for operating its crushers and stamps, and fuel can come only from long distances at enormous cost. A few miles from the mill there is a water-power, but the country between the two points is steep and rough, and for many months in the year is covered with snow. Electricity is the one means of getting the power from its source to the mill. The conditions are of the most favorable character for demonstrating the value and possibility of electrical transmission.

In this plant a Pelton wheel receiving water through a two-foot steel pipe, under a head of 320 feet, drives an alternating current generator. The current is carried over a line of bare wire to the mill, which is nearly three miles distant, and drives an alternating current synchronous motor of 100 h. p. The generator and motor are machines of the same size and form of construction as the dynamos at Portland, already described, and differ from these only in some minor modifications.

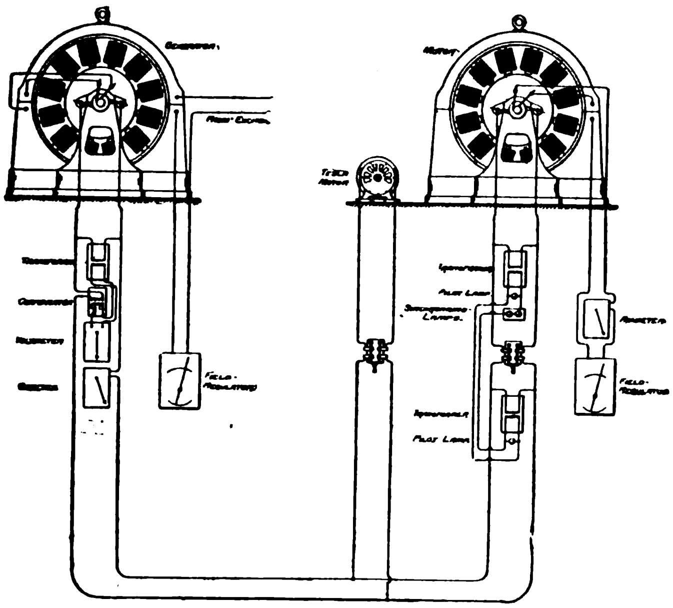

FIG. 4.

The generator is provided with a composite field winding, Fig. 4. A part of the magnets are excited by direct current from a separate machine, and the rest are excited by a current from the generator armature, which is proportional to the main current and is commutated by the equivalent of a two-part commutator. The adjustment is such that the E. M. F. on the main terminals rises as the current delivered by the machine increases, compensating for line losses and keeping the pressure at the motor 3,000 volts. The speed is 833 revolutions, giving 10,000 alternations per minute. The switchboard and regulating appliances are similar to those in the station at Portland. Ordinarily no adjustment is required after the machine is started, and the attendant has little to do besides looking after the mechanical running of the apparatus.

The motor, Fig. 5, is similar to the generator except in the manner of exciting the fields. The field current is obtained, not from a separate machine, but a second winding parallel with the main coils around the teeth of the armature. This current is commutated and passes through the field coils.

A motor of the synchronous type requires an auxiliary device for starting, which, in the present plant, is a small motor—a special modification of the Tesla type, Fig. 6. This motor comes quickly to its normal speed and then has ample capacity for bringing the armature of the large motor up to speed. Both of the machines are belted to a countershaft, and the ratio of the pulleys is such that the speed of the large motor is a little greater than that of the generator. The large motor is then excited and runs as a self-exciting alternating current dynamo at the normal E. M. F. of the circuit. The small motor is then switched off and the speed of the large machine gradually falls until it is approximately equal to that of the generator. The relation between the speeds of the two machines is indicated by the fluctuation in the intensity of lamps, which are connected in series with the secondaries of two converters, whose primaries are connected with the generator and motor respectively. At the time of slow variation and proper phase relation the machines are connected by closing the switch. The small motor is disconnected by its friction clutch and comes to rest, and the load is then thrown upon the large motor by a second clutch. The operation of starting requires but one man, and is accomplished in about two minutes.

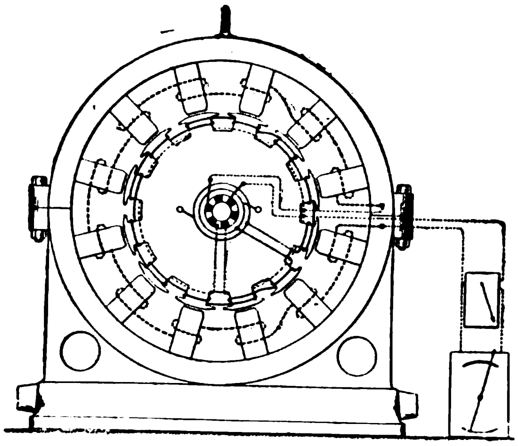

FIG. 5.

The connection of the motor to the generator is not a delicate operation. If the motor is running above synchronous speed at the time of connection with the generator it instantly adapts itself to the proper speed. If the motor speed is slightly lower than that of the generator it may fall into step when the switch is closed, but if it be running considerably slower it will not come into synchronism, but will further decrease in speed. When this occurs, the switch of the large motor is opened and that of the starting motor is closed, bringing the machine up to full speed again without any injury to the apparatus. If the E. M. F. upon each of the machines before connecting them be 3,000 volts it will remain unchanged when they are connected. If the field current of either machine be increased the E. M. F. will be raised, but the field current of the other machine may be lowered and the resulting E. M. F. made equal to 3,000 volts. The current flowing between the machines depends upon the relative field charges, and is least, whatever the load may be, when the two machines are equally, or very nearly equally, excited. The field current of either machine may be made zero, and the motor will still run, but with a greatly reduced capacity. In a test with machines of a smaller size the E. M. F. was 2,000 volts when the two field charges were equal. When the field charge of either machine was cut out it fell to 1,200 volts, and the current increased very considerably.

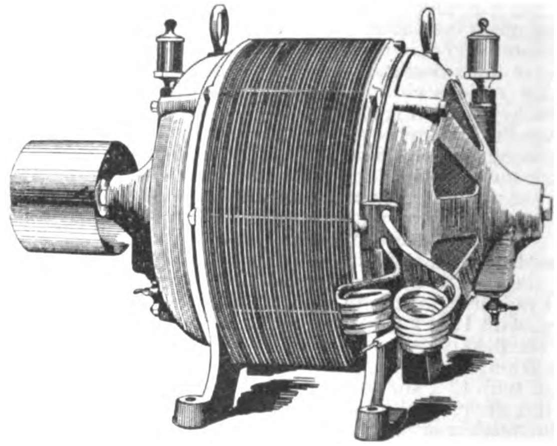

FIG. 6.

An efficiency test of the motor was made before shipment by driving a dynamo which was loaded. The current and E. M. F. received by the motor and delivered by the dynamo were measured and an allowance made for the loss in the dynamo. The full load efficiency in this way was found to be 93 per cent. In a test upon smaller machines of similar type the efficiency of the motor at full load was found to be 91.5 per cent. The efficiency of the synchronous motor system, leaving out loss in conductors, but including losses in generator and motor, in the plant for the delivery of 50 h. p. was found to be 83½ per cent. at full load, and 74 per cent. at half load.

Full load may be thrown on the motor suddenly. In the Gold King mill the stamps, which are operated by the motor, are usually left raised when the plant is stopped, in order to avoid the extra strain of lifting them when the plant is started. It sometimes happens that the stamps are left down and the motor is required to raise them all at once. When the clutch is thrown in, the current indicates that the load is considerably above the normal capacity of the motor, and yet it is started without difficulty or apparent strain.

The pole line runs from the power station up the mountain to a height of 2,500 feet, and then crosses a rough but comparatively level country to the mill. The line at some places is at an angle of 45 degrees, and many of the poles had to be set in solid rock. The surface of the snow in winter is occasionally at a level with the tops of the poles, and parts of the pole line are practically inaccessible during some months of the year. This region is peculiarly subjected to lightning discharges, and special precautions are necessary to protect the apparatus. In one instance there were 42 discharges of the lightning arresters in as many minutes.

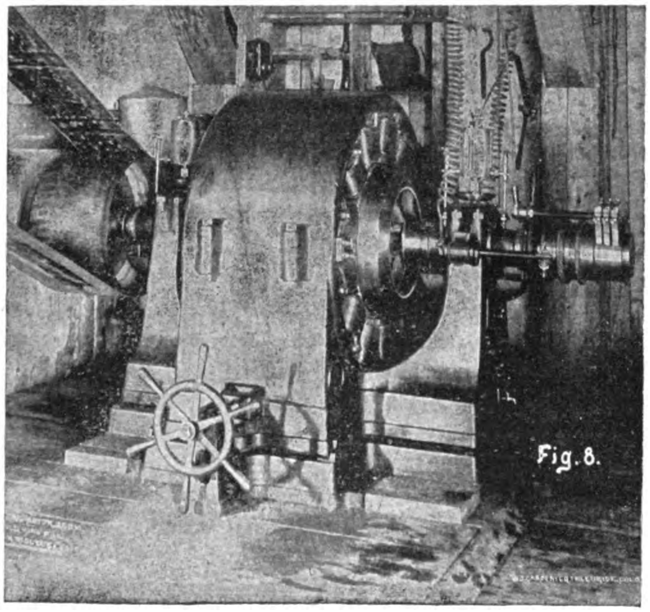

Fig. 8.

THE SYNCHRONOUS MOTOR IN THE GOLD KING MILL.

The plant was started for regular work in June of last year. An accurate record was kept from the middle of July to the first of May, showing the actual number and the length of the delays caused by electrical machinery. The aggregate time lost on account of the electrical apparatus was, by actual count, less than 48 hours during three-fourths of a year. Such a record as this, with a new type of machinery, in a country where line construction and maintenance are peculiarly difficult, with practically continuous service, with attendants who were not electricians, with a high voltage, a considerable distance and large power, places transmission by the alternating current synchronous system beyond the stage of experimental trial and gives it the stamp of commercial success.

This success is confirmed in a substantial way by the immediate extension of the plant. A 50 h. p. motor is now being installed at a mill a few miles from the Gold King. An order has been entered for a 750 h. p. generator to be located in the power station, and a 250 h. p. motor for operating a mill about 10 miles distant. Lighting at Telluride, eight miles from the station, which has been heretofore done on a small scale on a circuit from the power generator, is being extended. The large generator is of a new design, and is notable as it has more than three times the capacity of any alternating current dynamo previously made in this country. Two machines of this size have been running for some months for incandescent lighting in St. Louis.

This dynamo is of a type similar to the machines at Portland and Telluride. The field has 28 poles, requiring a speed of 570 revolutions for 16,000 alternations, the conditions of running at St. Louis, and 357 revolutions for 10,000, as it will be operated at Telluride. The armature has T-shaped teeth, as in smaller machines. The diameter of the armature is slightly over four feet and its length is about two feet. The total height of the machine is eight feet and its weight is 40,000 pounds. The electrical efficiency at full load is over 95 per cent.

The extension of alternating current working, both for lighting and power, by the use of larger machines is therefore already provided for. The extension to greater distances is largely a question of E. M. F. Nearly every one is familiar with the rapidity with which the cost of copper diminishes as the voltage is increased. If the cost be $100 with 500 volts it will be $25 at 1,000 volts, and $1 at 5,000 volts. The higher the tension, however, the greater the difficulty and cost of construction and the greater the liability to accident with apparatus and line. There are a few points in connection with this subject which may be noted without entering into a general consideration of it.

The smallest size of wire that can well be used for line work, on account of its mechanical strength, is about No. 6 B. & S. This wire will transmit with 20 per cent. loss 100 h. p. 10 miles at 4,000 volts, or twice the power half the distance. Unless these distances or powers are to be exceeded an increase in pressure would result in no saving in copper but simply in a less line loss, which is already not excessive.

The use of 4,000 volts at the motor and a line loss of 20 per cent requires an outlay for copper of only about 10 per cent. to 15 per cent. of the total cost of the plant when the distance is 10 miles. Unless, therefore, the cost of copper is to be an insignificant proportion of the total cost it is unnecessary to exceed this pressure unless the distance be greater than about 10 miles.

These simple considerations show that pressures practically the same as those employed in the plants which have been described are ample for considerable distances. The same type of apparatus which has been successful in them is available for larger capacities. The fundamental elements required for electrical transmission in a very wide range of cases have therefore been tried and their success demonstrated.

For considerably longer distances, where pressures higher than about 5,000 volts are required, good practice indicates the use of transformers for raising the pressure at the generator and reducing it at the motor, similar in general to those employed at Portland. The increased pressure thus available greatly reduces the cost of copper required, and this reduction must, of course, be more than sufficient to cover the cost of the transformers.

The alternating current motor has been one of the most complicated and difficult electrical problems, and yet the first large alternating current motor installed in this country excels direct current apparatus in simplicity of construction and operation, in perfection of regulation, and handles with simple sliding contacts, running for a week without adjustment, a pressure which with commutators is impracticable.

There is another class of alternating current apparatus to which no reference has been made. The multiphase, or Tesla system, which has attracted much attention of late, possesses the characteristics of this type of apparatus, which readily adapt it for combining simple construction with the use of high presures. There are also marked advantages in the characteristics of the motor which are of especial value where distribution of power is to be combined with transmission. Motors of this class are self-starting with load, and may be run either as synchronous motors or with one winding short-circuited and no commutator or brushes. The latter is the ideal motor in point of mechanical construction.

The simplicity, flexibility and range of the alternating current system make its possibilities the sole dependence of the largest enterprises, toward which the public and engineers are looking. The records of the plants at both Portland and Telluride, demonstrate that these possibilities are being realized, and that work in this field is fast passing from experimental investigation into practical electrical engineering.

UNIVERSITY OF WISCONSIN.

A DETAILED account of the electrical engineering course at the College of Mechanics and Engineering of the University of Wisconsin, at Madison, is given in the circular for 1892–3. The aim of the college is not to produce engineers, but men with great capacity for becoming engineers. A through curriculum is provided, under the direction of Dr. Davies and Prof. Jackson, in the theory of electricity, in addition to which the laboratory practice is made to conform with and illustrate in a thorough manner the instruction by text-books and lectures. Of the total number of hours given to instruction in the electrical engineering subcourses nearly one-half (about four hundred and fifty hours) is devoted to work in the laboratories. The results derived by students in the laboratory, together with a full description of the work performed, and the methods employed, are reported to the professor on blank forms furnished for the purpose.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIII. NEW YORK, JUNE 15, 1892. No. 215.

We have no sympathy with the cant of the day with reference to "practical men" if by this term is understood those who act without reference to well-established general laws and are only guided by empirical rules or undigested experience.—Joseph Henry.

PROF. HOUSTON ON CEREBRAL RADIATION.

FEW theories of modern times are more suggestive and full of scientific interest than that recently advanced by Prof. Edwin J. Houston as a possible explanation of hypnotism, telepathy, mesmerism and kindred phenomena, while the fact that its author is a man equally well known in the world of science and that of affairs, affords a striking instance of the catholicism of fin de siècle research. That a mysterious "something" exists, enabling one mind to exert absolute power over others apparently in tune with it is universally admitted, but the study of its nature has been too long left in the hands of visionaries. While Prof. Houston modestly confesses that his suggestions are incomplete, and, in fact, characterizes them as rather wild, they open an enormous field for labor upon lines already familiar to men skeptical as to spooks, but intensely alive to the importance of all that bears upon the questions of everyday life.

Postulating the existence of luminiferous ether capable of passing readily through the densest matter, Prof. Houston argues that cerebration, if attended by vibrations, must develop in this ether wave motions, having the brain atoms as centres; that is, the act of thought necessitates atomic disturbance and a consequent expenditure of energy. The various groupings of the brain cells would appear to correspond with certain combinations of thought, and vice versa; thus study, by causing the constant repetition of the same set of motions, gives the brain particles a tendency to form groups more or less permanent, which call up the particular train of thought to which they belong. The existence of this atomic vibration of the brain cells, while not distinctly proven, is far from unlikely, and, indeed, certain facts seem to point very strongly to its probability. A fracture of the skull, for instance, producing abnormal pressure on the brain will suspend cerebration until the pressure is relieved, when the patient usually takes up the thread of life from the moment when consciousness was lost, without regard to the intermediate lapse of time.

An active brain is, then, regarded as sending thought waves through the ether in all directions, like a conductor through which an oscillatory discharge is passing, and the possibility of the transference of specific cerebral vibration from it to a passive brain is explained by the action of sympathetic vibrations, as illustrated in the well-known experiments with tuning-forks and the phenomenon of the radiation of light. Electric resonance presents a still more striking instance of sympathetic vibration, where an oscillatory discharge from one conductor traverses space with the velocity of light, and, upon meeting a circuit so tuned as to be in consonance with the original conductor, sets up oscillations in this circuit identical with those that excited it.

If thought radiations partake of the nature of ether waves their phenomena should, naturally, correspond with those of thermal, luminous, electric or magnetic radiation, and it becomes possible to imagine the refraction of a complex train of thought, so to speak, by something corresponding to a prism; nay more, the author suggests even the remote possibility of obtaining photographic impressions of thought waves on a suitably sensitized plate or its equivalent, and the subsequent utilization of such a record to awaken in another brain thoughts identical with those recorded. The image thus produced would convey no more meaning to the eye than do the marks on the cylinder of a phonograph, but the idea of such an instrument is, after all, no more preposterous than that of the phonograph, or even the telephone, would have appeared one century ago.

Such, briefly outlined, is the theory that Prof. Houston, with many assurances that it is merely a suggestion, and, it may be, some misgivings that it is ahead of its time, has offered to scientists interested (and who is not?) in the countless phenomena of thought transference. That he should have sufficiently overcome his diffidence to make public the result of these speculations, in which, he says, he has indulged for a number of years, is a subject for congratulation; it is, however, to be hoped that he will not be content to stop at suggestions.

THE EDUCATION OF THE ELECTRICAL ENGINEER.

"As ye sow, so shall ye reap," is a maxim, the truth of which needs no exemplification. Its force, however, is nowhere more apparent than in everything that relates to educational matters. At the meeting of the Institute at Chicago two papers, one by Prof. D. C. Jackson, and another by Prof. R. B. Owens, were devoted to the discussion of the proper training for the electrical engineer, and the views expressed therein are worthy of the most serious consideration. It must be evident to any one at all acquainted with the requirements of active practice, that no school, however well equipped it may be with able teachers and complete laboratories, can turn out finished engineers ready to cope successfully with the new problems in electrical engineering which are daily presented; or, indeed, to plan immediately and carry out work even of the most general character. In this respect electrical engineering does not differ from any other department of engineering; but in a branch as modern as that of electrical engineering the preliminary training ought to be specially thorough, because the many precedents and large accumulated experience of the past which can be drawn upon in other departments of engineering are not at the elbow of the electrical engineer. Prof. Owens makes a distinction between various classes of electrical engineers, basing his differentiation on the varied character of the work of the designing and the constructing engineer, and suggests the arrangement of the courses of study with a view to affording each of these classes the best course of training. Prof. Jackson has done well to call special attention to the necessity of stimulating and fostering the exercise of the student's judgment, and more particularly his common sense; and this reminds us forcibly of the saying of a celebrated engineer that every engineering formula ought to have a coefficient, "K," standing for common sense. We are not quite prepared to agree with those who take the stand that electrical engineering is nine-tenths mechanical engineering, for although the work of the mechanical engineer enters, to a considerable extent, into some departments of the electrical engineer's work, it nevertheless does not occupy that ratio of importance which some of the adherents of this theory would seem to attach to it. The subject is one which is worthy of the most serious consideration and may well engross the attention of all engineers.

THE STANDARD CENTRAL STATION.

If the electrical census which is now being prosecuted with vigor under the superintendence of Mr. Allen R. Foote accomplishes no other object it will have earned its right to the thankful recognition of the electrical community by pointing out many examples of how not to do things, and more particularly how not to build and operate an electric light and power station. It is fortunate that Mr. Foote has called to his assistance so intelligent an investigator as Mr. Horatio A. Foster, who, in his paper read before the American Institute of Electrical Engineers, at Chicago, showed how many stations were, from their very inception, handicapped by bad engineering and worse management. To expect a profitable business under such conditions would, of course, be asking too much, and hence the reason why not a few electrical enterprises have turned out unsatisfactorily. On the other hand Mr. Foster showed how a well-designed station, operated by competent men, is a source of more than average profit. The remedy which he suggests for mitigating the existing evil is the employment initially of a competent electrical engineer. He deprecates in no unmistakable terms the usual method of installing a plant by paying visits to certain prominent electric light stations, without other guidance than possibly that of the representatives of the selling companies themselves, and the choosing of a plan of construction from among a mass of undigested information gathered on such trips. While Mr. Foster's suggestion that the Institute, in connection with the National Electric Light Association, should lay down a set of rules and plans for a standard electric light station is one well worthy of consideration, the question seems pertinent whether the art has yet arrived at such a permanent state as to make such a step desirable at this time. The opinions of many competent men are still so at variance that it would appear problematical whether plans could be adopted, which would meet the views of even a majority of the electrical engineers of to-day.

ALTERNATE CURRENT LONG-DISTANCE TRANSMISSION.

The Chicago meeting of the Institute, besides its just claims as one of the most successful, thus far, in the career of that body, may also lay claim to having been the first to bring out a paper describing the practical operation of a long-distance alternate current transmission plant run "for business." We have heard and read so much about what *could* be done with the alternating current that it is doubly refreshing to learn what has actually *been* done. Mr. C. F. Scott's paper describing the Telluride plant is therefore of more than ordinary interest. He rightly lays stress upon the fact that even with the comparatively low potential of four thousand volts a large field of operation is within the scope of practical long-distance transmission, which, of course will be largely enhanced when we are able to handle higher potential. While the plan described is unquestionably successful, it might be claimed by some that such an installation does not combine all the elements of a successful system for general distribution of power by alternating current. But even if such were the case, there is a sufficiently large sphere of usefulness for the system as it stands to make its exploiting profitable to those engaged in this work.

ELECTROLYTIC REFINING OF COPPER

The air of mystery that has for a long time surrounded the processes for the electrolytic refining of copper is, we are glad to note, being removed and in a manner which leaves no room for doubt that in the near future this industry will occupy a leading position in the electric arts. Prof. Badt points out in his Institute paper that the principles are well established, and with proper attention to details success in this field is assured. With the immense mineral resources of the United States, which have already made it the largest copper-producing country in the world, it is not difficult to foresee the time when we shall supply foreign markets with electrolytically refined copper. That this can be done profitably is evidenced by recent shipments of such copper abroad, so that the producer is not entirely dependent upon home markets for the disposal of his product.

The meeting of the American Institute of Electrical Engineers in Chicago, last week, was a most decided success, and that which made it so was the heartiness of the welcome given it by Western members and friends. An excellent programme of papers was discussed and enough work went over to start the fall season with an afternoon and evening session.

SERIES ELECTRIC TRACTION.[1]

BY NELSON W. PERRY, E. M.

In railway practice, it is the distance rather than the quantity of current that forms the most important factor of increase, though the latter cannot be neglected in planning for the future. In street railway construction, assuming the distance to remain the same but the traffic to double, the amount of copper required to maintain the same relative economy must also be doubled. This is a minor matter as compared with the case where both distance and traffic are doubled. In this latter case, to maintain the same economy the weight of copper must not only be doubled but squared. The limit of extension even on these lines is, however, soon reached, and the only recourse, by existing methods, is to erect at or near the further point another generating station, with all that that implies in the way of additional investment in real estate, machinery, etc., and a duplicate set of employees.

In long lines, the bugbear of the multiple arc system of distribution is the drop in potential at the further end. There are two remedies for this drop in potential at hand—either to increase the amount of copper in the feeders, which within commercial limits is but a partial remedy, or to increase the pressure, using the same amount of copper which, when the multiple arc method of distribution is employed, introduces as many difficulties as it obviates. There is still a third remedy, and that is, to employ the constant current method, in which, under all circumstances, the current remains the same and the pressure varies as the work performed.

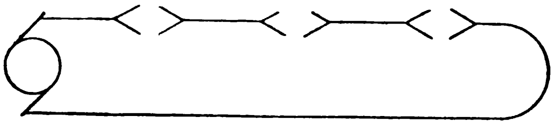

FIG. 1.

In the one case the copper must vary as the demands and distances—the pressure remaining the same, and in the other the pressure varies, the copper and current remaining the same.

If energy can be so much more advantageously distributed to long distances by the constant current method for arc lamps, why should this method not commend itself to the ever-increasing distances to which our electric street railroads are reaching? If the steam locomotive is ever to be supplanted by the electric motor, why should not this method of distribution be the one to be adopted? The answer is that the constant current method, as heretofore developed has not been sufficiently elastic to meet the requirements, and although the generation of a constant current involved much less complex machinery, and the cost of distribution to distant points necessitated a much smaller initial outlay, still the difficulties introduced by this method largely outweighed all its advantages.

It is my purpose to show how the constant current system may be made as elastic in every way, at least on paper, as the constant potential, without sacrificing in any way any of the advantages peculiar to the system, and how it is possible to make each unit in such a system nearly, if not quite, as independent of every other unit as is the case in the system now in vogue.

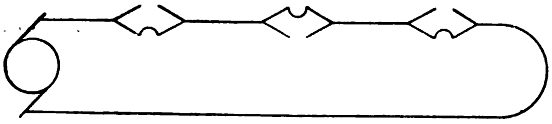

FIG. 2.

The system which I am about to explain may properly be described as consisting of a circuit interrupted by a series of breaks in multiples of two. Or one consisting of a circuit interrupted by breaks in multiple series with each other—the breaks being in multiples of two. The conception then would be like Fig. 1. But in order that a current shall pass around this circuit, it is necessary that *one* of the breaks in each multiple shall be normally closed. It matters not which one is closed, so our plan would now look like Fig. 2.

If a translating device should successively occupy each of these breaks, it would receive current during the time that its terminals connected the ends of the two broken wires, in proportion to the relative conductivity of the two paths open to the current. But we are not satisfied to have a portion only of the current pass through our motor—it is necessary that *all* the current must so pass. We must, therefore, make the resistance of the other branch infinite during the time in which the motor is bridging, through its terminals, the break, or, in other words, the normally closed branch must be broken.

If, therefore, we place an electromagnet in *series* with the normally broken branch, so that when vitalized it will open the switch in the normally closed branch, and allow it to close again by gravity or otherwise, when the magnet is devitalized, we have provided in a crude way for operating traveling translating devices in series. Our conception now would be represented somewhat by Fig. 3.

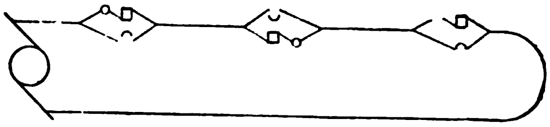

FIG. 3.

By this arrangement, the moving device only receives a momentary impulse as its terminals touch the ends of the break, and would have to rely upon its acquired momentum to carry it to the ends of the next break. It will be apparent, however, that it is immaterial whether the device receives its next impulse by closing the next break in the circuit or whether it skips that one and gets it from any other break, either on that circuit or from one connected with an entirely different dynamo. It is this feature that permits the use in my system of sidings on single-track roads, and of forks (the skipping of one or more breaks), and the intercommunication between separate circuits (the jumping from a break on one circuit to a break on another).

It is desirable, however, that the moving device be impelled by as nearly a continuous force as possible, instead of by a succession of momentary impulses. Instead, therefore, of having the ends of the normally open break face each other, as represented heretofore, we may extend these wires for some distance parallel with each other, and our plan assumes the form shown in Fig. 4.

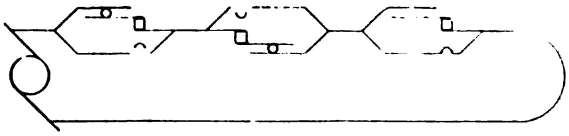

FIG. 4.

It is also desirable that the interval of time during which the device is without current, viz., that occupied in passing from one break to the next, shall be as small as possible. This naturally suggests having the normally open breaks all on the same side of the normally closed breaks, and if these parallel wires be continued so as to overlap those constituting preceding and succeeding breaks, a car or other moving translating device may pass from one break to another without even momentary interruption of current. In Fig. 5, the lower line which I call the "feeder," contains all of the normally closed breaks, represented by mercury cups normally connected electrically by a fork taking into them, which constitutes a double-pole switch actuated by an electromagnet in the manner to be described.

The upper pairs of wires, which it will be seen are merely the parallel extensions of the other possible path for the current, are in multiple with the path through the mercury cups. One of each of these pairs of wires, which will hereafter be denominated sections, is connected to the feeder wire on one side of the mercury cups, and the other has a similar connection on the other side. The two wires of each section normally without electrical connection with each other, constitute what has been termed the "series of breaks normally open." If, however, these two wires be connected electrically through the terminals of a motor, the latter will be in multiple with the mercury cups and momentarily receive only the current due to the relative conductivity of the path thus offered. By the arrangement shown in Fig. 5 the electromagnet which opens the mercury cup switch is in series with

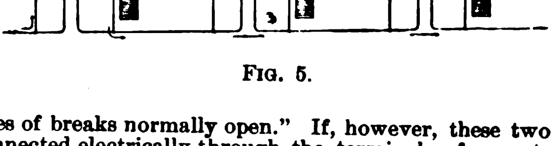

FIG. 5.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 8, 1892.

the motor circuit, and the latter no sooner receives current than the former is actuated, the switch is opened and the whole of the current which was momentarily divided between the two branches, is diverted to the motor.

If the corresponding wires of the succeeding sections be caused to overlap without making electrical connection with each other, and these laps be staggered, as shown, a means is provided whereby the motor prepares the succeeding section for occupancy before wholly passing out of the one it is about to leave and accomplishes this without interruption to the current. Figs. 6 and 7 show how this is done and the arrows show the paths taken by the current as the transition takes place. When the motor is in the position represented in Fig. 5, there is but one path for the current, viz., around the open switch in the feeder and through the electromagnet by which it is kept open, back again to the feeder.

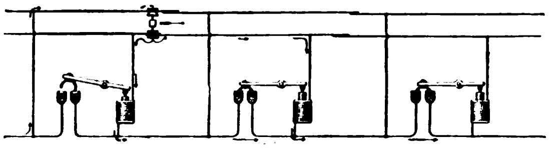

FIG. 6.

As the motor proceeds to the right, one of the terminals first embraces the lower lap, thus offering two paths for the current, one passing through the switching arrangement that controls the section the car is about to leave, and the other through that controlling the section it is about to enter (see Fig. 6). As it progresses still further this terminal passes beyond this lap at about the same time that the other terminal embraces the other lap. This leaves the first switch without current and the succeeding switch is automatically opened. There is no break in the circuit, however, even during the short interval occupied by the two switches in acting, for while the further terminal embraces the further lap, both of the switches concerned are short-circuited, as shown in Fig. 7. Before the further terminal has passed beyond the lapping portion of the two succeeding wires, the first switch will have closed and the succeeding switch will have been opened, thus diverting all of the current to the section upon which the motor has now entered.

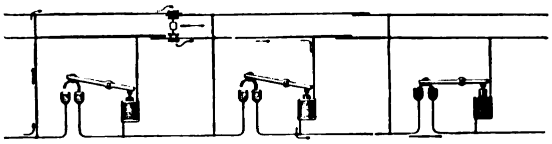

FIG. 7.

On single-track roads where turnouts are required, the turnout constitutes merely an additional section to one side of the main line, which is skipped by the car keeping the main track, and taken by the other car in passing. It, like every other section, has its own individual controlling switch, and when both the main track and siding are occupied by cars their motors are arranged in series with each other. We have thus provided a means by which a car may leave one section on a given road and enter another one on the same or another road without breaking the main circuit, *provided the car is always going in the same direction*. In all of the cuts thus far, the car is supposed to be going from left to right, and the switches are arranged accordingly; but, if we examine the drawings again, it will be found that in the plan suggested in Figs. 5, 6 and 7, if the car were going in the opposite direction, the circuit would be momentarily broken as it left one section and would fail to divert the current to the section it was entering. In a second plan the car is momentarily without current whenever it passes from one section to another.

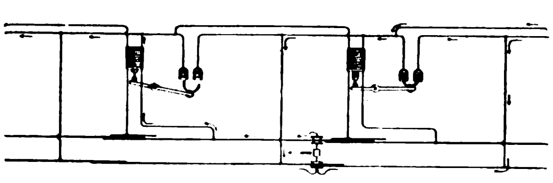

FIG. 8.

By combining these two plans, however, all of the difficulties seem to be removed. Figs. 8 and 9 show how this combination is effected, and the courses of the current when the motor terminals are in different positions on the wire. It will be noticed that, as in the first plan described, the trolley wires of adjacent sections are lapped, and that these laps are staggered; that parallel to, but insulated from, the nearer laps, is placed the subsidiary wire which short-circuits the switch to the right. The switch-controlling magnet, as is shown, has two coils wound cumulatively, and may be operated either by the current passing through the subsidiary wire, by that passing through the nearer trolley wire, or by both when it takes both paths.

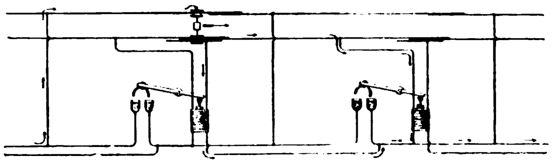

FIG. 9.

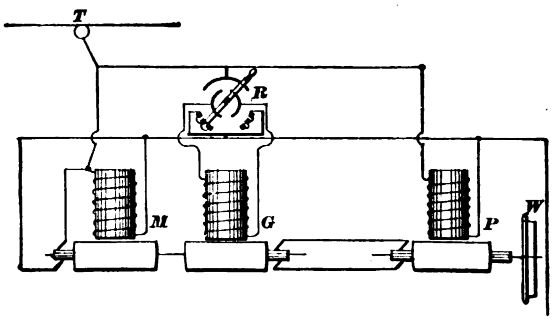
A NEW SYSTEM OF ELECTRIC PROPULSION.[1]

BY H. WARD LEONARD.

IF we could operate from the constant potential system a shunt-wound motor running at a constant speed and could interpose between this motor and the axle some device equivalent in its effect to an infinite number of different sets of mechanical gears, so that we could make use of any reduction desired, it would enable us while using a constant power to increase the torque as we decreased the speed, and *vice versa*, which is just what is desired in railway practice where the least torque is required when at full speed on the level, and the greatest torque is required at the slow speed in starting and in operating on a grade. Numerous and very ingenious devices have been invented for accomplishing this variable mechanical reduction, but on account of the complication, noise and unreliability they have never proved successful.

The writer has recently devised an electrical method of securing all the results which could be obtained from such a set of gears described, with a freedom from the noise, wear, complication and rigidity which such a set of gears would necessarily involve.



LEONARD SYSTEM OF ELECTRICAL PROPULSION.

T, trolley.
M, motor portion of power converter.
G, generator portion of power converter.
P, the propelling motor for the car.
R, the regulating and reversing rheostat in field of G.
E, the connection to ground.
W. the car wheel.

Following is a general description of the arrangement proposed, as indicated by the accompanying diagram.

Each axle is driven by a gearless motor, either directly or by means of a connecting-rod. The fields of these motors are excited directly from the constant E. M. F. of the line and independently of the armature circuit. Beneath the car and between the axles there is suspended a motor-generator, each armature winding being in a separate field. The motor portion of the motor-generator—which will, for convenience, be called the power converter—is shunt wound and connected just as a shunt motor is for use upon ordinary constant potential circuits. The field of the generator portion of the power converter has its field connected across the line and has inserted in it a regulating and reversing field rheostat. This field circuit is independent of the armature circuit. The generating armature of the power converter is in metallic connection with the armatures of the gearless propelling motors. It will be noticed that this circuit including the armature is a distinct and separate metallic circuit having no connection with the line in any way.

---

[1] Abstract of a paper read June 8th, 1892, at the general meeting of the American Institute of Electrical Engineers in Chicago.

Suppose now that our shunt motor is running at full speed and that our controlling rheostat in the generator field circuit is at its central position, so that the generator field circuit is broken. Although the generator armature is being driven at full speed it is revolving in a field having no magnetism except the residual magnetism, and hence produces practically no volts. Let us now move our controlling switch so as to place the generator field across the line, but with a resistance in series with the field, of ten times the resistance of the field coils. We now get a slight excitation of the field and a development of volts at the brushes of perhaps 40 volts. This voltage will produce a current through the armatures of the driving motors dependent upon the ohmic resistance of this circuit only; and hence, even at this low voltage, a large current will be produced, which being in a field of full strength will cause a torque sufficient to start the armature. The speed of the armature will, of course, be governed by the counter E. M. F. which its revolution produces in its strong field; and hence, just as in the case of a shunt-wound motor, its speed will be practically constant so long as the E. M. F. supplied is constant.

If we now gradually increase the magnetic field of the generator by cutting out resistance by moving the controlling switch, we will gradually raise the E. M. F. of the armature circuit, and with it the speed of the driving motors. Since these armatures are revolving in a constant field, the torque they produce will be exactly proportional to the current in them, and the current will automatically flow exactly as is required to produce the necessary torque to maintain a speed such that the counter E. M. F. will approximately equal the E. M. F. supplied by the power converter. Thus it will be seen that the speed of the car will be dependent upon, and proportional to, the E. M. F. supplied by the power converter, and the torque or tractive effort will be dependent upon, and proportional to, the current supplied by the power converter

Let us suppose that 60 amperes flowing through the armatures in fully excited fields will produce a torque sufficient to move the load when upon a grade. It is evident from what we have seen that 40 volts from the power converter will produce this current. Hence, by an expenditure of 2,400 watts in the secondary circuit, or a total power, including field excitation, etc., of about eight h. p., we can start a fully loaded car upon a grade.

Under the existing systems, we would need the same 60 amperes in the same fully excited field, but would necessarily use the full voltage of 500 volts, and, therefore consume energy represented by 30,000 watts, as against possibly 6,000 in this system. The current from the line in starting the car under ordinary conditions by this system would be about 12 amperes at 500 volts, instead of from 60 to 100 amperes at 500 volts.

It will be evident from what has preceded that with this power converter system we can propel a car upon any practicable grade with a consumption of power no greater than is required to operate the car at full speed upon a level, by merely reducing the speed to the required extent. In street railways of from five to ten cars, this is of great importance, for it means that we can equip a road with about six h. p. per car, as regards the engines and dynamos, and that our conductors can be reduced to about one-third of the amount at present necessary, for we will never require more than 20 amperes at the distant point, where to-day we have to provide for 60 amperes with the same loss and same initial E. M. F.

Under the rheostat system the plant is severely taxed when an unusual crowd must be moved from a certain point, and it is then, when it is of the greatest importance that no break-down should occur, that it usually does occur. With this power converter system we could, upon a five-car road, start up and move with perfect safety 10 or even 20 cars from the most distant point on the road, though of course at a reduced speed, but the crowd would be handled with perfect success and without subjecting any portion of the plant to any unusual strain.

In the large cities it is no unusual sight to see an electric car moving at the slowest possible speed for perhaps several blocks. Perhaps 12 amperes are required to obtain the necessary torque. This at 500 volts is 6,000 watts. The power required for this slow motion by the proposed system would not exceed one-fifth of this amount.

Following is a tabulated statement (Table I) showing the results we may expect to obtain by this system in operating with fully loaded car under three different conditions: First, at 12 miles per hour on level; second, at three miles per hour on five per cent. grade; and third, at one mile per hour on level.

LEONARD SYSTEM OF ELECTRICAL PROPULSION.

TABLE I.

Duty of Car. Showing various losses expressed in watts.

Various losses involved.	8 tons at 12 miles per hour on level.			8 tons at 3 miles (or 5 tons at 5 miles) per hour on 5 per cent. grade.			8 tons at 1¼ miles per hour on level.		
	Full speed, ⅙ full torque; armature current, 10 amperes.			¼ full speed, full torque; armature current, 60 amperes.			⅒ full speed, ⅙ full torque; armature current, 10 amperes.		
	Power converter.		Driving motors.	Power converter.		Driving motors.	Power converter.		Driving motors.
	Mot'r part	Gen. part.		Mot'r part.	Gen. part.		Mot'r part.	Gen. part.	
Field	250	275	250	250	60	250	250	25	250
C^2R in armature	160	60	60	250	2,000	2,000	20	60	60
Friction	60	60	120	60	60	30	60	30	10
Foucault currents, hysteresis, etc	200	400	400	200	50	50	200	10	10
Total	670	795	830	760	2,170	2,330	530	125	330
Total watts wasted	.....	2,295	....	......	5,260	.....	......	985	.....
Watts of work done	......	4,000	....	......	6,000	.....	......	400	.....
Total watts absorbed	......	6,295	....	......	11,260	...	......	1,385	.....
Amperes at 500 volts	......	12.6	....	......	22.5	.....	......	2.8	.....

In arriving at the losses, as indicated, the motor part of the power converter has been assumed as having the following features: E. M. F. 500 volts, current capacity for 10 hours continuous duty, 15 amperes; resistance of shunt field winding, 1,000 ohms, armature resistance, 1.1 ohm.

The generator portion of the power converter and the driving motor are assumed as having the following features: E. M. F. 500 volts; current capacity for 10 hours' continuous duty, 40 amperes; resistance of field 900 ohms; armature resistance, 0.55 ohm.

The rolling friction with gearless motors on good level track is assumed as 20 lbs. per ton. Car is assumed to be eight tons in weight fully loaded and five tons for moderate load.

We find that with 12 tons moving at 12 miles per hour on a level we will require 12.6 amperes which is practically the same as by present series motor systems. With eight tons moving at three miles per hour upon a five per cent. grade 22.5 amperes will be required, which is about one-third of the power required by present systems. With eight tons at one mile per hour on level 2.8 amperes will be required, which is about one-fifth of by present systems. With five tons moving at five miles per hour on five per cent. grade 18.5 amperes will be required, which is about 40 per cent. of the power required by present systems.

The author then showed the various advantages accruing from the use of the proposed system, basing his figures on the statements and results obtained by various writers and experimenters on electric railways, and which are tabulated in Table III.

The comparative first cost of a railway of moderate size, say, from five to ten cars equipped by present systems, and by the proposed system, giving the detailed figures per car are given in Table II.

TABLE II.

Showing probable comparative first cost per car by present and proposed system.

	Present system,	Proposed system.
Steam plant, generators and conductors per car (steam plant 1,000; generators, 700; conductors, 500)	2,200	1,100
Motors (two 15 h. p. equipments)	1,800	1,400
Power converter	0	900
Controlling switches, cables, rheostats, etc	200	30
Total first cost per car	4,200	3,430
Saving in favor of proposed system per car		$770

Table III gives a summary showing the features of the proposed system as compared with the corresponding features of the present system.

TABLE [illegible]II.

	Present system.	Proposed system.
First cost of steam plant, generators, conductors and car equipment per car.....	$4,200	$3,430
Amperes at 500 volts required to start full load on level....	75	2.8
Amperes at 500 volts for full load at full speed on level. .	12.5	12.5
Amperes at 500 volts to start full load on 5 per cent. grade..	125	10
Amperes at 500 volts for working speed on 5 per cent. grade	60	22.5
Amperes fed back to system in coming down 5 per cent. grade..............................	0	10
Pounds of coal per car per hour.........................	50	25

The features of the proposed system which seem, at first sight, to be very objectionable are: The increased cost of the car equipment and the fact that we are adding an additional machine, having two fields, two armatures and three bearings; but, as we have seen, there is only an apparent increase in the first cost, for the saving in the generators and distributing plant far exceeds the additional cost of the car equipment; and the use of the motor-generator for elevators, traveling cranes, etc., has demonstrated that, as regards the attention it requires and the depreciation it suffers, it has a marked advantage over the rheostat or commutated field used in the present methods of operation.

NINTH GENERAL MEETING OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS, CHICAGO, JUNE 6, 7 AND 8, 1892.

THE ninth general meeting of the Institute began in Chicago on June 6, at 10:30 a. m., at the Grand Pacific Hotel. The proceedings were opened by President Sprague, who called Mr. T. D. Lockwood to the chair.

The first business taken up was the reading by Mr. Carl Hering of a paper by Dr. Louis Duncan, of Johns Hopkins University, entitled "Some Experiments on Alternating Currents." Dr. Nichols remarked that the paper showed how much progress had been made in this work. A short time ago it would have been thought extremely good work to get such readings of the E. M. F. and current curves in, say, an hour, but here they had been taken in five minutes, and thus their simultaneity prevented any possibility of change in the conditions. Prof. Carhart told of some similar work he had done recently.

The next paper was one by Prof. H. S. Carhart, of the University of Michigan, on "The Relation between the E. M. F. of a Standard Clark Cell and the Density of the Zinc Sulphate Solution." It has been known for a long time, said Prof. Carhart, that the E. M. F. of a Daniell cell decreases with increase of the density of the zinc sulphate solution. The same is true of a standard Clark cell. When the solution is saturated at a higher temperature than the one at which the cell is to be used, the zinc sulphate crystallizes out as the temperature falls and again goes into solution when the temperature rises. As the increase of density causes a decrease in E. M. F., changes of temperature are accompanied by variations in the E. M. F., due only indirectly to the temperature changes. These variations have been included in the temperature coefficient. His own cells, remarked Prof. Carhart, are made with a solution saturated at a temperature lower than any at which the cell will be used. Hence the density does not change by this crystallization process and the temperature coefficient is reduced to half its former value. To ascertain the effect of changing the density of the zinc sulphate through a wide range, two of his students, Messrs. Cheney and Barnum, have made cells with solutions ranging in density from 1.036 to 1.429 at 20° C., and have ascertained that the E. M. F. varies from 1.485 volts to 1.438 at 15°, or something over 3.2 per cwt.

Mr. E. G. Willyoung added a few words as to the great degree of accuracy maintained by the Clark cells prepared under the Carhart method.

The next paper was read by Charles E. Emery, Ph. D., the well-known engineering expert of New York, on "Rational and Empirical Formulæ Showing the Relation between the Magnetomotive Force (*H*) and the Resulting Magnetization (*B*)." In this very interesting paper, the theory that magnetization is the circulation of an etheric atmosphere was examined by the law of the flow of fluids, with the gratifying result that a rational fluid function was developed, corresponding very well with the observed *H.-B.* curves of magnetization, and which, moreover, showed decidedly phenomena equivalent to those of magnetic saturation. The observed results indicated a more intense action during the earlier stages of magnetization than was provided by the fluid function; but the writer showed that the theory of molecular magnets appeared quite sufficient to account for such intensified action. The work of Weber, Maxwell, and Ewing on the last-named theory was reviewed at some length, and as an additional feature, Dr. Emery showed strain curves derived from the compression of steel almost identical in appearance with *H.-B.* curves of magnetism. He then remarked that action at a distance requires etheric force, that the fluid function identifies the motion as translatory rather than vibratory, and that, therefore, he considered the fluid function the important one; and that the molecular magnets only intensified the initial action. The first part of the paper closed with a discussion of the effect on existing theories as to the nature of light and electricity in case magnetism be definitely identified with etheric flow or circulation. The second part of the paper was entirely practical, giving empirical formulæ applicable to the tables given by Thomson and to the results of experiments made more recently by Steinmetz. Elaborate tables on different bases and in different units will accompany the formulæ in the printed paper. The paper was very well received, and many regrets were expressed that it had not been received in time to allow of its discussion in printed form.

The last paper read at the morning session was presented by Prof. E. L. Nichols for PROF. Geo. S. Moler, of Cornell University, on "A Dynamo Indicator or Instantaneous Curve-Writing Voltmeter." This instrument is intended to be used in tracing those curves which show the changes in potential of the two ends of a single coil of the armature, and also those showing the changes between one brush and one of the commutator bars, as the armature revolves. It consists in the main of a very rapidly vibrating needle of a voltmeter and a smoked cylinder against which the pointer is made to press at the required moment. The curve is traced during a single revolution of the armature, and is then easily transferred to paper. The voltmeter which is enclosed in the body of the little instrument is of the permanent magnet type. This paper elicited compliments to Prof. Moler, the main criticism being that of Prof. Crocker, who objected to the small range of amplitude of the curves shown, but means for enlarging the range were suggested by Profs. Nichols and Roberts and Dr. Emery.

The morning session was then adjourned.

The afternoon session of Monday was devoted to a visit to the Pullman Works, a special train having been provided by the Illinois Central R. R. Co. A large number of members went on this trip.

In the evening the meeting was held at the Chicago Electric Club, which has recently moved into new quarters and seized this opportunity of welcoming the Institute. The handsome parlors of the club were filled to overflowing. President B. E. Sunny, of the Chicago Club made a most cordial and felicitous address of welcome, and then introduced President Sprague, who read as his inaugural address to the Institute a paper on "Coming Developments in Electric Railways. It was a masterly exposition of the difficulties and problems incident to the heavier work now opening up before the electrical engineer, and won universal encomiums by its conservative though hopeful statement of the case. It is printed elsewhere in this issue. The paper was followed by a brief discussion, in which Ex-Mayor Cregier, Dr. Emery and Mr. T. D. Lockwood participated. A lunch was then served.

The Tuesday morning session was begun with President Sprague in the chair, and was continued under the chairmanship of Mr. Carl Hering. The first paper presented was one on "The Magnetic Permeability of Special Irons for Electrical Purposes," by Messrs. M. L. Thompson, P. H. Knight and G. W. Bacon of Cornell University. A number of curves, which went to prove the desirability of steel castings, were shown with this paper, which elicited a discussion from Messrs. Carhart, Nichols, Emery, Bradley and Jackson. The last named said it was matter of regret that these interesting tests had not been accompanied by chemical analyses, showing the effects of the varying proportions of carbon and manganese, or even from the introduction of aluminum.

A short paper was then presented by Prof. B. F. Thomas of the Ohio State University, entitled, "Notes on Wiping Contact Methods for Current and Potential Measurement." It was an interesting little sketch of work done as far back as July, 1880, at Stevens Institute on a Brush arc machine, with a tangent galvanometer for the current measurement and a condenser and Thomson galvanometer for the potential. In 1885 Prof. Thomas used the method again on a Thomson-Houston arc machine, substituting a Thomson portable electrometer with Leyden jars to increase its capacity, for the condenser and galvanometer, preferring them to all other instruments for high-potential curves.

In the discussion, Mr. Scott referred to the use of the telephone on alternating machines. The telephone was so delicate that it gave what was not wanted as well as what was wanted, but it was easy to tell the click peculiar to the contact.

Prof. Thomas then read another paper on "A Life and Efficiency Test of Incandescent Lamps," based on work done under his direction by Messrs. P. Martin and R. H. Hassler of the Ohio State University. These tests were made with 10 lamps of the ordinary 16 c. p. 110 volt type, of the A. B. C., Beacon, Columbia, Economic, Packard, Pennsylvania, Standard, Thomson-Houston, Edison, Perkins, Sawyer-Man and Steuben makes. The results were embodied in a series of curves, which. however did not take into account the question of price. The lamps in these curves were designated by letters. A number of facts were apparently brought out. For instance, one of the curves showed that the lamps on the average grew dim at a steady rate, falling off 90 per cent. in about 200 hours, to 68 per cent. in 600 hours, ending at a little less than 55 per cent. at 1,200 hours. Another plate of curves of all the lamps, showed an average initial value of 4.2 watts per candle rising to 5 at 300 hours, 5.9 at 600, 6.8 at 900 and 7 at the end. As to the time when lamps became "dead," if the time of decease were set at 50 per cent. of initial c. p., the lamps tested passed 1,000 hours on the average and certain makes ran up to 1,200. With the limit at 75 per cent., on the average all died at 450 hours. Prof. Thomas added that for the consumer to-day, the average lamp lasted at its fair value for about 230 hours, when they were past their prime. He added that one very remarkable feature brought out by the tests was the unquestionable freedom from blackening shown by lamps exhausted mechanically as compared with those exhausted on the familiar mercury pumps. Several such lamps were shown. Mr. J. W. Howell attackedthe paper very vigorously on various grounds. He pointed out that, strange to say, no 3-watt lamps had been included, and he regarded as utterly fallacious any tests based on 10 lamps of a make. Only a series of tests running through thousands of lamps would give a fair result for any manufacturer. As for some long-life lamps, he mentioned a case where he found an eternal lamp running on a 98-volt circuit. On taking it from its proud possessor be found it marked 108 volts. Mr. E. P. Roberts backed up Mr. Howell's criticisms to some extent.

A paper by Mr. H. A. Foster on "Some Points for Electrical Engineers" was then read by Mr. T. C. Martin, who pointed out that although 100 central stations, nearly all in a single State, had been visited by the writer. not a single mention had been made as to storage battery work by any of them. This contrasted strongly with the large use of storage batteries in European central stations. Mr. H. Ward Leonard also made some pithy remarks as to the gross mistakes made in central station design and location, and the economic value of the electrical engineer in this field of work.

The afternoon session of Tuesday, with President Sprague in the chair, was largely occupied by three very important papers on electric mining: "Electric Coal Mining Machinery," by Mr. Elmer A. Sperry; "The Electric Percussion Drill in Theory and Practice," by Mr. Henry R. Marvin; and "Long-Distance Transmission for Lighting and Power," by Mr. C. F. Scott. The first paper was an admirable discussion of the various features of bituminous coal mining in the West, and of Mr. Sperry's electric mining machinery designed to meet the special conditions. The amount of work done by Mr. Sperry was a surprise to almost everybody, while his ingenuity well deserved the praise bestowed on it by President Sprague. Mr. Marvin next pointed out the severe requirements imposed on electric percussion drills, and held that the solenoid and plunger afforded the simplest solution of the problem—his own methods being fully described. Mr. Scott's paper, to be found elsewhere in this issue, was an interesting description of the work done at Telluride, Col., with a Westinghouse alternating synchronous plant.

The session was brought to a close with the reading of the paper on "Railway Train Lighting," by Mr. A. H. Bauer, electrical engineer of the Pullman Company. This paper was printed in The Electrical Engineer last week.

The evening session was held at the rooms of the Chicago Electric Club. President Sprague in the chair. Mr. F. Upton and Mr. T. C. Martin, of the special committee on an improved method of electing officers of the Institute, filed a report embodying a system of letter ballot. It was referred to the next general meeting, accompanied by an informal vote of approval. A paper was then read by Prof. R. B. Owens, of the University of Nebraska on "Electro-Technical Education," and another was read by Prof. D. C. Jackson, of the University of Wisconsin, on "The Technical Education of the Electrical Engineer." Both were heard with closest attention by a large audience, and were freely discussed by Prof. Crocker, Messrs. Sprague, Sperry, Bradley, Lockwood, Emery, Upton, Perry and others.

A paper was then read by Mr. C. E. Carpenter, of St. Paul, on "A New Form of Resistance." This resistance takes the shape of very fine wire laid on an iron sheet and held irremovably thereto by a coating of enamel. The capacity of current reception and of radiating surface combined is enormous. Mr. Carpenter showed the special advantages of this compact device for stationary motor rheostats, street cars, stage regulators, etc., and exhibited some forms. He also shows the adaptation of the same idea to heaters, flatirons, small kettles, etc., and passed current through a number of them to illustrate their quickness and usefulness.

The morning session on Wednesday, was called to order by President Sprague, and Mr. T D. Lockwood then read his able and exhaustive paper on "Selective or Individual Signals," printed in the last issue of The Electrical Engineer.

This was followed by a batch of three papers on electric railway work: "Electric Railway and Motor Tests," by Prof. G. D. Shepardson and Mr. E. P. Burch, of the University of Minnesota; "Series Electric Traction," by Mr. Nelson W. Perry. and "A New Form of Electric Propulsion," by Mr. H. Ward Leonard. The paper by Prof. Shepardson detailed some tests of railway motors but its chief value lay in the curves which went to contradict the commonly accepted notion as to the straightness of the load line, as they showed tremendous fluctuations in the space of two or three minutes with a load of from 1,000 to 1,500 amperes. Mr Perry's paper rehearsed the experience with the Short series system, now abandoned, and argued that it was still possible and desirable to use a constant current method, of a nature very ingeniously worked out by Mr. Perry himself, with consequent saving in copper, etc. Mr. Leonard's paper dealt with a most ingenious and striking plan for utilizing a motor generator on the car, as the result of which the speed of the car would be dependent upon and proportional to the E. M. F. supplied by the power generator, and the torque or tractive effort will be dependant upon and proportional to the current supplied by the power converter. As a consequent result also from this method, for example, the current required from the line in starting the car would be about 12 amperes at 500 volts instead of from 60 to 100 amperes at 500 volts. Mr. Leonard argued that in his plan the increase in cost of equipment was more apparent than real, while the saving in current and the reduction of extreme loads was very considerably on the side of economy.

All three papers attracted attention, and the discussion excited was so active that it was deemed best to postpone it until the fall, when it will be taken up at an early meeting. Dr. Emery, Prof. Thomas, Messrs. Sprague and Leonard, all took part. Mr. Sprague having called Mr. H. L. Webb to the chair, addressed himself to a very animated discussion of the points involved, doubting the accuracy of some of the Shepardson figures, altogether discrediting the series system as a "back number" or "lost cause," and expressing a belief that Mr. Leonard's method when tried would be found wanting. Mr. Leonard replied and the discussion was then adjourned.

Dr. James B. Williams, of New York, then read a very interesting paper on "Oil versus Air as Insulation," in which he reported a number of experiments going to upset entirely the idea as to the higher insulating qualities of oil—so far as they went. The paper was not presented in print, and its discussion was therefore adjourned until the fall, when Dr. Williams will repeat his experiments before the Institute not only with air and oils but with a number of the leading insulations now known to commerce.

The facts set forth in this paper were obtained wholly from experiments and tests made by the doctor in New York City and by himself and his brother R. W. Welty in California while they were making the investigation of insulating material and its uses which is now being described in a serial in this journal. These experiments and tests were made with special apparatus designed and made by Dr. Williams for testing insulating material by means of charges of high potential; and the results obtained are worthy of careful consideration on account of the perfection of this apparatus. The potential of the charges used was about 2,300 volts. The results show that, when used to insulate conductors carrying high tension *constant* currents: 1. Air even with a humidity of 80 per cent. is far superior to oil. 2. That air is superior to pure paraffine. 3. That steam will conduct such currents, but is superior to oil. 4. A film of oil on glass and porcelain will not prevent surface leakage. 5. Oil, if placed on paraffined hard rubber, at once ruins the surface insulation of that material. Other subjects treated of were: 1. The expansion of oil in pipes or tubes. 2. The use of fibrous material in combination with oil. 4. Absorption of moisture by oil.

Reference was also made to some new forms of insulated conductors invented and patented by the doctor, in which dry air in combination with other insulating material is used to form the dielectrics thereof.

The meeting then adjourned.

On Wednesday afternoon through the thoughtfulness of the local committee, and the energy of Mr. F. De Land, the members and a large number of friends, making a party of about 100 were enabled to pay a special visit to the World's Fair Grounds and view the work now going on there. The Illinois Central Railroad provided a special train, and at the grounds another special observation train was found ready, with escorts. The party was accompanied by a large number of ladies, and was also favored with the guidance of Prof. Barrett, commissioner, and Dr. Allan V. Hornsby, secretary of the Electrical Department. Nearly all the buildings were inspected, and three cheers were given for the huge Electricity Building, now about half finished. The party were also given an opportunity of seeing, in the Forestry Building, several of the pieces of statuary that are to adorn the various edifices. The tour of inspection occupied fully two hours, and not a single visitor came away without a feeling of pride and admiration regarding the scope of the work, the magnificence of the design, and the manner in which the whole plan is being carried out. The electrical engineer who does not visit Chicago in 1893 will have occasion to regret it.

The thanks of the members were specially due to the local committee comprising Messrs. E. M. Barton, chairman, C. A. Brown, W. A. Kreidler, Chas. Wirt, and Dr. Elisha Gray; also to the Chicago Electric Club, which kept open house for all the visitors during their stay. Among the invitations received and accepted were those from the Pullman and Western Electric Companies, the Love conduit electric railway system, and the Sperry Electric Mining Co. Messrs. Brown and Warner placed their sloop yacht at the disposal of members, several of whom were glad to get a view of Chicago from the lake. The Illinois Central R. R. Co. also did the handsome thing in providing the Institute with special railroad facilities, free of charge.

After the convention several of the members proceeded further West to Denver to take part in the gathering of Railway Telegraph Superintendents. Among those were Mr. T. J. Smith, of the E. S. Greeley & Co., accompanied by Mrs. Smith, Mr. and Mrs. T. D. Lockwood and son; Mr. S. S. Bogart, and Mr. R. W. Pope.

THE following is a list of those in attendance:

E. P. Burch, C. S. Bradley, E. M. Barton, C. A. Brown, M. J. Buckley, S. S. Bogart, J. F. Barclay, Prof. F. B Badt, P. P. Beals, Prof. H. S. Carhart, C. L. Cornell, G. Cutter, W. B. Cleveland, Prof. F. B. Crocker, W. A. Cothren, E. Caldwell, A. H. Cowles, J. F. Connor, W. F. Collins, C. H. Dunbar, F. De Land, Leo Daft, M. A. Edson, Dr. Chas E. Emery, S. D. Flood, C. R. Gilman, J. H. Gregg, Carl Hering, M. S. Howard, F. S. Hunting, A. L. Hadley, John W. Howell, R. S. Hill, C. C. Haskins, E. M. Hughland, Prof. D. C. Jackson, Capt. A. de Khotinsky, J. Kettlestrings, T. D. Lockwood, L. V. Lindon, H. Ward Leonard, H. N. Marvin, C. K. McFadden, F. P. Mills, T. C. Martin, E. A. Merrill, Percy Martin, J. W. McCrosky, R. J. Miller, Prof. E. L. Nichols, Prof. R. B. Owens, J. J. O'Connell, M. O'Dea, R. F. Outcault, A. F. Oppermann, R. W. Pope, G. M. Phelps, Frank C. Perkins, Nelson W. Perry, C. W. Parks, W. M. Porter, E. P. Roberts, Frank B. Rae, W. D. Ray, Prof. G. F. Shepardson, J. R. H. Staley, C. F. Scott, L. L. Summers, Frank J. Sprague, M. B. Speir, B. E. Sunny, A. Strate, W. N. Smith, E. A. Sperry, M J. Sullivan, E. F. Seixas, T. J. Smith, C. F. Street, C. M. Sames, Prof. B. F. Thomas, F. R. Upton, E. G. Willyoung, Herbert Laws Webb, Dr. J. B. Williams.

COMING DEVELOPMENT OF ELECTRIC RAILWAYS.[1]—I.

BY FRANK J. SPRAGUE.

IT is a trite but mistaken saying that electricity is in its infancy. It dropped its swaddling clothes when Morse sent the first telegraphic message. It put aside dresses and pinafores when the dynamo machine and arc light were invented. The incandescent lamp, the telephone, the art of welding, the transformer, are incidents of buoyant youth; the modern electric motor and electric railway mark a vigorous manhood.

The truly marvelous development of electric applications of every kind, the accomplishment of many things which in ignorance of the very art, or lack of knowledge of what are now well-known facts, and more particularly the great commercial development of the transmission of power, whether for stationary purposes or for electric railways, has led many to foolish prediction and idle boast.

This is no age of inspiration, nor time for hopes never to attain fruition. It is above all things a practical age, perhaps too practical, but nevertheless one in which commercial enterprises to be successful must promise either a new field of development or economies in older fields.

As the orthodox few have been waiting in sublime faith for many centuries, and will wait for many more for the fulfilment of ancient prophecies, so too will impracticable electric enthusiasts vainly wait for the millenium when investments are boundless, performances limitless and efficiencies unity.

It would perhaps have been proper in making my inaugural address to so representative a body as that of the American Institute of Electrical Engineers that I should touch upon the special discoveries and experiments which have recently attracted attention, but there have been so many enthusiastic and brilliant workers that neither the time at my disposal nor the knowledge I possess would permit me to do justice to their work; hence it seems better to take up a subject with which I have been more particularly identified, which to-day commands so much attention and concerning which there are such conflicting opinions. While finding encouragement in the past achievements of our profession, I think the time opportune for a word of caution.

Electric street railways are no longer experimental nor is their success problematical. Their history for the past five years is that of an almost unequaled development. Almost within a decade has occurred the first working of a practical electric railway. In a third of that period there have been put in operation, or are under contract, more than 450 roads, equipped with nearly 6,000 cars and over 10,000 motors, and with over 3,000 miles of track. There is made a daily mileage of not less than 700,000 miles, and over a billion of passengers are carried annually. At least $75,000,000 have been invested in this industry alone. Thirty thousand horses in a single year have been relieved from the slavery of street car propulsion; stables are disappearing and streets becoming cleaner; luxurious cars are running on smooth, well-built and rigid road-beds. Dividends have been increased, expenses reduced, investments enlarged; the unproductive has become productive, the impossible possible. Land values have been increased, habitable limits extended, homes created and time saved.

We no longer hear seriously of the dangers of the trolley wire, the failures of service. The time has come when legitimate investment is amply warranted. Electric street railway construction has become a matter of engineering, not experiment. Not only have the smaller towns adopted what is the only available means of current supply, but the larger cities are following their example. St. Louis and Baltimore, Minneapolis and St. Paul, Buffalo and Rochester, Boston and Brooklyn have fallen into line, and latterly even Philadelphia seeks an improved street service, and in New York public interest is being aroused.

The general feeling of opposition to poles and wires, ought not, however, to act as a barrier to such reasonable and proper introduction of an overhead system of supply, as the conditions now existing in that city very properly warrant. I have frequently pointed out the fact that the greatest good can come to the greatest number, especially in the over-burdened condition of transit which there exists, if certain of the lines were electrically equipped; wherever, in fact, there would be no street obstruction. On streets occupied with elevated structures, these structures themselves could be used for a practically rigid overhead system.

Among the numerous places in New York where an overhead system could be put in perfect operation are Central Park West, the Boulevard from Fifty-ninth street up, a part of the First and Second Avenue lines; the Third, Sixth and Ninth Avenue lines, and all the suburban extensions in the annexed district. I am not sufficiently familiar with the streets of Chicago, which is the last other remaining city which must consider electric street railways.

In these larger cities, however, one condition should be insisted upon, and if this condition is met in the proper spirit then much of the objection which has been raised against an overhead system must necessarily disappear.

The construction must be of the very best. The only overhead line allowed should be a contact wire with sufficient strength; the main conductors and the feeders should be put underground in proper conduits. There would then be overhead only a wire necessary for the smallest duty and of the requisite strength. In many streets, of course, the cable will hold its own until an electric conduit or surface contact system shall be proven satisfactory.

Impressed by the great development of this industry, and brought face to face with the changes it has wrought, the query is continually made—will the electric motor replace the steam locomotive? It is similar to the older questions, Will the telephone replace the telegraph? Will the electric light annihilate the gas system? And in all soberness a like answer can be made: "It will not; but it will, as the electric light and as the telephone have done, create a field of its own, and will replace a portion of the service now done by steam."

It seems to me that the growth of electric railways will proceed something in this order. First, the street systems in the various towns; then connecting lines between adjacent towns following the lines of highways; then longer connecting lines, either on the tracks of existing steam lines, or, growing bolder, on exclusive rights of way on the same order. Then will come suburban traffic on a larger scale, and freight transfer systems, and finally the more ambitious projects of trunk-line service under limiting conditions, such as I will specify.

It has been very properly said that a man will make the first long ride on electric railways by transferring from one town system to another through connecting links, rather than on individual roads. This is precisely the process by which great steam systems have been built up, although, of course, starting on a larger scale; and it is but natural that this shall be one step in the development of electric railways.

But evidently this natural process of evolution does not offer scope enough for the more enthusiastic, and we are now and again treated to an ideal electric road to be built on plans boldly defying both geography and the abodes of civilization.

An air line route according to rules of surveying allowed only in Russia and on the desert of Sahara; abolition of grades and street crossing; rigid and continuous rails; loaded cars of light weight, each operated by its own motor and making few or no stops; unlimited potentials and undiscovered resistance to insulation; new physiological and engineering laws; indestructible machinery; unheard-of powers of braking and new methods of train operation and signaling; around all, a clear atmosphere; above all, a perpetually smiling heaven, and behind all the unlimited bank account of the investor,—such are some of the characteristics of such a road. But perhaps it is but fair to ask, Given some of these conditions, what would be the capacity of steam traction?

---

[1] Presidential address delivered at the Chicago meeting of the American Institute of Electrical Engineers, June 6, 1892.

Letters to the Editor.

THE INSULATION RESISTANCE OF INTERIOR CONDUITS.

If insulation is not a desirable factor in electric wiring then let iron or other metal pipes be employed. If, however, insulation is a good thing, I presume the electricians with brains will admit that you cannot have too much of it. In this connection permit me to call the attention of your readers to the subjoined report of Prof. Crocker, of Columbia College. It has been my aim to obtain the highest possible insulation consistent with economical manufacture. This report indicates the measure of my success. If, perchance, a more fanatical insulationist than I exists, I have no objections to his "seeing my ante" and "going me one better" by employing the best insulated wire the market affords and putting it in my tubes.

EDWD. H. JOHNSON.

NEW YORK CITY, June 9, 1892.

(Copy.)

ELECTRICAL ENGINEERING DEPARTMENT,
COLUMBIA COLLEGE,
NEW YORK, June 8, 1892.

MESSRS. THE INTERIOR CONDUIT AND INSULATION CO.,
42 Broad street, City.

Dear Sirs.—I have tested a sample of your regular form of tubing with the following results:

A ten-foot length of tubing has an insulation resistance of thirteen thousand two hundred and fifty (13,250) megohms at five thousand (5,000) volts electrical pressure. The insulation was tested between the brass tube or sheathing which usually surrounds your insulating tubing, and a brass pipe fitting tightly inside the insulating tube. I applied the 5,000 volts pressure a great many times for considerable periods of time, and also applied 5,500 volts pressure without the slightest lessening of the perfection of the insulation.

The voltage was obtained from a special continuous current dynamo. This is a more practical and probably a more severe test than using a static charge, which latter is the ordinary method of making high voltage tests of insulation.

I believe that the insulation would stand even a much higher voltage without breaking down.

Yours truly,
(Signed) FRANCIS B. CROCKER.

LEONARD'S NEW THREE-WIRE SYSTEM.

UNDER the title "A New Three-Wire System" there appears in your issue of June 8, 1892, a description of certain arrangements or devices which were worked out by Mr. E. W. Rice, Jr., and myself some time ago and practiced a considerable time ago.

Mr. Leonard in his article does not distinctly claim the new three-wire system, but he leaves it to be inferred that the system, is one of his own invention. I may be pardoned therefore, for calling his attention to the fact that what he shows in his Figs. 3, 4, 5 and 6, has been anticipated by us and combined with other improvements, such as transfer switches for transferring the compensating counter-electromotive force machines or apparatus from one side to the other of the three-wire system, at will.

The counterpart of Mr. Leonard's Fig. 3 in which the storage battery is used as a counter-electromotive force device on one side of a three-wire system is found in Fig. 6 of my patent No. 360,125, dated March 29, 1887, to which I refer Mr. Leonard for confirmation. The counterpart of Mr. Leonard's Fig. 4 is found in Fig. 1 of the patent to Mr. E. W, Rice, Jr., No. 460,364, dated Sept. 29, 1891, and the machine shown by Mr. Rice has the advantage over those shown by Mr. Leonard in that it is compounded for drop. The arrangement shown in Mr. Leonard's Fig. 5 has its counterpart in the joint patent to E. Thomson and E. W. Rice, Jr., No. 468,123, dated Feb. 2, 1892, with the improvement that the machines corresponding to B and C of Mr. Leonard's figure are combined in a motor-generator which is compounded for drop and requires therefore no hand regulation of field. Mr. Leonard's Fig. 6 is an extension of the same idea to a double three-wire system. Attention is also called to my patent No. 468,122, which in Fig. 1, shows an arrangement like that of Mr. Leonard's Fig. 4, except that the machines are compounded for drop and that automatic devices are employed to transfer the machine corresponding to C in Mr. Leonard's figure to the lightly loaded side on which the highest potential exists, so as to keep it a motor at all times.

An inspection of the documents mentioned will, I think, display the fact that the system set out by Mr. Leonard had been more fully worked out by ourselves, and while our systems may not have been in existence long enough to entitle them to be called "old," they are certainly not new in the sense in which they appear in Mr. Leonard's article.

ELIHU THOMSON.

LYNN, MASS.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED MAY 31, 1892.

Alarms and Signals:—

Contact-Post for Electric Bells, F. W. Manger and O. H. Huebel, 475,783. Filed Feb. 29, 1892.

Employs a bifurcated contact post fastened to the base plate.

Automatic Fire-Alarm System, C. Burgher, 475,925. Filed Jan. 29, 1892.

Conductors, Conduits and Insulators:—

Insulator-Pin, F. M. Locke, 476,207. Filed Jan. 30, 1892.

Claim: The combination with an insulator of a post having a vertical recess clear across the outer end and a layer of soft material interposed between the insulator and the post.

Electric Conductor, C. W. Bassett, 475,990. Filed Feb. 1, 1892.

Employs an insulation of seamless paper over which is placed a second protective cover.

Distribution:—

System of Electrical Distribution, C. O. Mailloux, 475,877. Filed Nov. 25, 1891.

Provides for the control and regulation of pressure at different parts of a system without loss of efficiency.

Dynamos and Motors:—

Dynamo-Electric Machine, W. Koedding, 476,151. Filed Jan. 31, 1891.

Has for its object a very low rate of speed and great initial force in all positions of the armature.

Galvanic and Thermo-Electric Batteries:—

Secondary Battery Electrode and Process of Making the Same, A. Reckenzaun, 475,797. Filed Sept. 13, 1890.

Has for its object the production of active material upon the surfaces of plates by means of the electric arc.

Lamps and Appurtenances:—

Incandescent Lamp, J. Ball, 476,183. Filed Nov. 23, 1891.

Relates to incandescent lamps having two filaments either of which is available for use as circumstances require.

Device for Testing Arc Light Circuits, A. H. Manwaren, 476,156. Filed Feb. 3, 1890.

A device for ascertaining while the lamps are burning how many are in operation, and also to detect and locate grounds on the circuit.

Electric Light Shade, H. A. Miner, 476,021. Filed Dec. 31, 1890.

Seal for Leading-In Wires, H. D. Burnett, 475,998. Filed March 7, 1892.

Employs a yielding support for the leading-in wire near the point where it enters the glass.

Railways and Appliances:—

Safety Attachment for Railway Trolleys, M. A. Yeakley, 476,028. Filed April 7, 1891.

Automatically draws down the trolley in case the latter accidentally leaves the wire.

Conduit for Electric Railways, W. F. Carr & C. F. Ferrin, 476,128. Filed August 6, 1891.

Employs removable arch blocks detachably secured together and held in position by lugs.

Hanger for Electric Railway Wires, C. B. Elliott, 476,192. Filed Nov. 30, 1891.

Employs a shell provided with a protecting cap and having an annular water shed protecting the insulating material in which the hanger is embedded.

Swivel Pull-Off for Overhead Wires, C. B. Elliott, 476,193. Filed Nov. 30, 1891.

Provides means for enabling the members of the supporting device to be adjusted with relation to each other.

Electric Railway Motor, J. F. Shawhan, 475,970. Filed May 10, 1890.

Claim 1 follows:

A combination with a car axle of a motor supported thereon, the said motor consisting essentially of two electromagnets and two armatures, the armatures being connected with the axle.

Railway Signal System, W. G. Wattson, 475,955. Filed June 17, 1891.

An electric block system.

Telegraphs:—

Telegraphy, T. Gothorpe, 475,988. Filed August 15, 1889.

Has for its object to produce a more equal variation of potential at the distant end of a line.

Telephones and Apparatus:—

Telephone, E. M. Harrison, 476,200. Filed August 9, 1890.

Employs an elliptical diaphragm having its edges free.

Telephone, S. F. Sherman, 476,026. Filed March 2, 1892.

Employs a variable resistance made of a piece of carbon creased or folded to form plaits.

Submarine Telephone, H. Finch, 476,207. Filed Oct. 23, 1891.

Claim 1 follows:

A telephone comprising an electromagnet embedded in a water-resisting compound.

Measurement:—

Electric Meter, O. Ericsson, 475,759. Filed July 23, 1891.

Employs a lever and pawl through which motion is transmitted, a cam to move the lever and another cam controlled by the measured current.

Miscellaneous:—

Electric Wire Holder, E. L. Lloyd, 475,781. Filed August 6, 1891.

Employs an engaging hook and loop clasped upon the insulator.

Telephonograph, J. P. Magenis, 476,054. Filed July 23, 1891.

Employs a phonographic cylinder in which the pressure of the stylus is augmented by magnetic attractions instead of gravity.

Wire-Gauge, C. J. Nifler, 476,057. Filed Dec. 29, 1891.

Consists of a cam-shaped plate and a pivoted arm having a notch near the outer end for the purpose of holding the wire to be gauged between it and the plate.

Electric Terminal, H. Sanche, 476,060. Filed Sept. 29, 1891.

Has for its object to provide a terminal with which the denuded portion of the wire may be readily connected and which will be held with complete protection to the cut end of the insulating covering.

Electrical Reciprocating Tool, W. P. Carstarphen, Jr., 476,225. Filed June 1, 1892.

Employs a reciprocating plunger moving within the tubular spools of two sets of coils through which a direct current is alternately passed.

Electric Self-Winding Clock, F. M. Schmidt, 475,809. Filed Oct. 9, 1892.

Coal-Cutting Machine, I. Wantling and J. T. Johnson, 475,833. Filed Nov 25, 1891.

A duplex rotary coal-cutter in which the two rotating cutters turn in opposite directions.

Rheostat, F. W. A. Schneider, 475,898. Filed July 20, 1891.

Consists of saponified fat in a suitable casing interposed in a circuit and fitted with terminals.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

You may knock under to the heat, but your "ad" is just as effective in hot weather as in cold.

THE "L. P. & D." SYSTEM OF DRIVING DYNAMOS.

Readers of The Electrical Engineer will remember short articles that have from time to time appeared in its pages in regard to the unique method of power transmission devised by Messrs. Perry & Demeritt, of Montpelier, Vt., and will be interested in a more detailed description of the system.

In the accompanying illustrations the diagram, Fig. 1, shows the position of the driving device and transmitting pulleys which may be changed to meet the requirements of any particular station, so long as the relative position of the driver, transmitting pulley and belt remains the same. It can be arranged to belt up or down and the direction of rotation may be reversed, although the better arrangement is as shown. This system can also be used when the smaller pulley is on the motor and the larger one is driven; but in any case the slack side of the belt which may be long or short as desired must clear the larger pulley.

It is plain that with this arrangement of belt and pulleys a dynamo or other machine may be stopped or started by moving in the proper direction either of the pulleys encircled by the belt. This gives a very flexible system. It can be used everywhere that a straight belt can, at the same time being claimed to give a greater driving power; but its best point is shown at close quarters where the other would not work at all.

In designing this transmitter, the aim was to produce a machine that would make the dynamo independent, and when the belt was at rest, to have the driving pulley and shaft free from contact with any part of the transmitter or belt. This desirable end has been attained, and the operation seems to compare very favorably with any other device for stopping and starting. Another idea was to use as few parts as possible and to embody in these the best mechanical principles in operation. The success of the transmitters shows the wisdom of this policy.

The following is related of the first machine installed: "When it (the machine) was set up and belted to a dynamo its friends were anxiously watching the operation of starting and stopping, which was very successful. As the wires for loading the dynamo were being arranged, the inventor explained that he expected to help out the belt wrap on the driving pulley by pressing the transmitter pulley against it. The machine was started up and 'pinch' applied. Circuit after circuit was thrown on until the capacity of the dynamo was reached, when they found they were getting fifteen per cent. more work out of an eight-inch belt than could be obtained in straight belting and the dynamo bearing ran cool. But the noise from the two pulleys pinching the belt was terrible; so as a further test the pinch was removed until the transmitting pulley ran quietly, when to the surprise of all the belt still carried the load steadily, showing no signs of slipping."

With the belt contact as shown in Fig. 1, or any similar arrangement of belt and pulleys giving a belt wrap four times the diameter of the driven pulley upon the driver, the belt will slip first upon the driven pulley; thus the driving power is calculated by the belt speed and contact on driven pulley. There is claimed for this device increased belt power with less friction on bearings than any other system, together with equally good control of dynamo; also that it is as easy to set up and as cheap to maintain as the best, while its economy of space is strikingly shown in the station plan, Fig. 2. Here are six 2,000 c. p. 50-light T. H. arc dynamos, with all shafting, pulleys, bearings and six "L. P. & D." power transmitters, installed on a floor space of 17 feet 2 inches, including two cut-off couplings. Each dynamo can be started or stopped independently of the others. The dynamos are two feet apart, giving ample room to operate each machine. When the dynamos are not running, the main line pulleys are entirely free from any contact whatever with dynamos or belting.

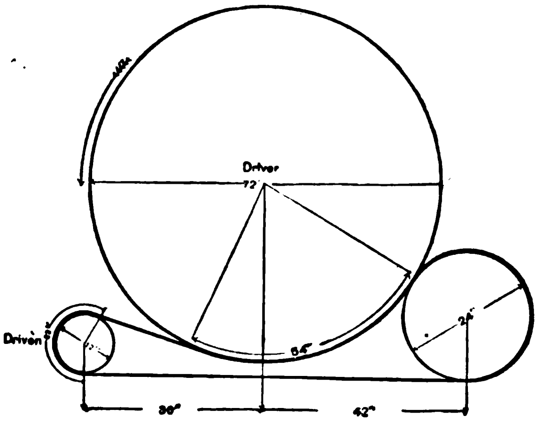


Fig. 1.

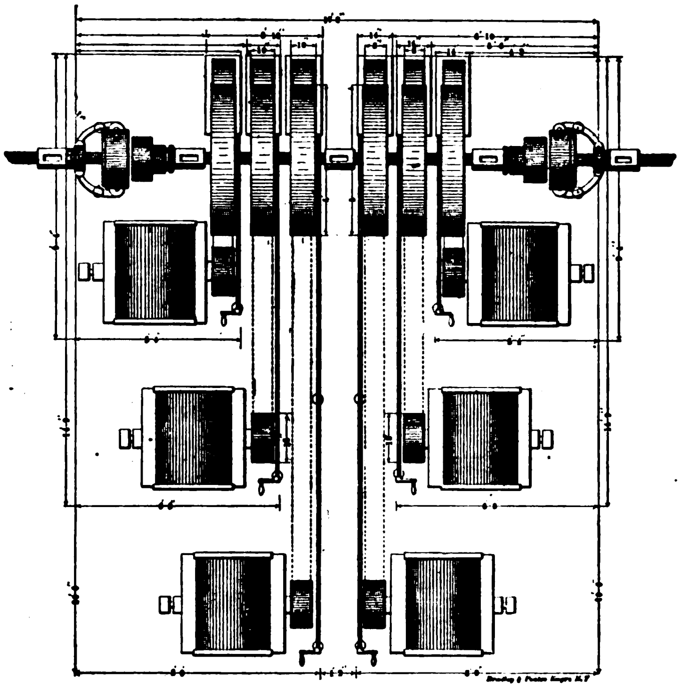

Fig. 2.

BALL ENGINE CO.

The Ball Engine Co., of Erie, Pa., report the following recent sales:

Santa Cruz Electric Light and Power Co., Santa Cruz, Cal., 200 h. p. tandem compound; Hotel St. Louis, Minnetonka, Minn., 60 h. p. simple engine; Risdon Iron Works, San Francisco, Cal., 200 h. p. cross-compound, two 200 h. p. tandem compound, 85 h. p. simple engine, 50 h. p. simple engine, 60 h. p. simple engine; Sandusky Electric Light Co., Sandusky, Ohio, two 130 h. p. simple engines, 100 h. p. simple engine; Portland Railway Co., Portland, Me., 250 h. p. simple engine; East Liverpool Western Electric Co., East Liverpool, Ohio, 200 h. p. simple engine; Hotel Stratford, Philadelphia, Pa., 50 h. p. simple engine; Cooley & Vater, Minneapolis, Minn., 60 h. p. simple engine; Electric Light Co., St. Peter, Minn., 100 h. p. tandem compound; Fremont Electric Light and Power Co., Fremont, Col., 80 h. p. simple engine and steam plant complete; Middlesex County Workhouse, Boston, Mass., 130 h. p. simple engine; Riverside Knitting Mills, Cohoes, N. Y., 35 h. p. simple engine; Johnson Company, Johnstown, Pa., two 300 h. p. simple engine, 200 h. p. simple engine, 100 h. p. simple engine; Jackson Gas Light Co., Jackson, Miss., 100 h. p. simple engine and steam plant complete.

RIES SOCKETS.

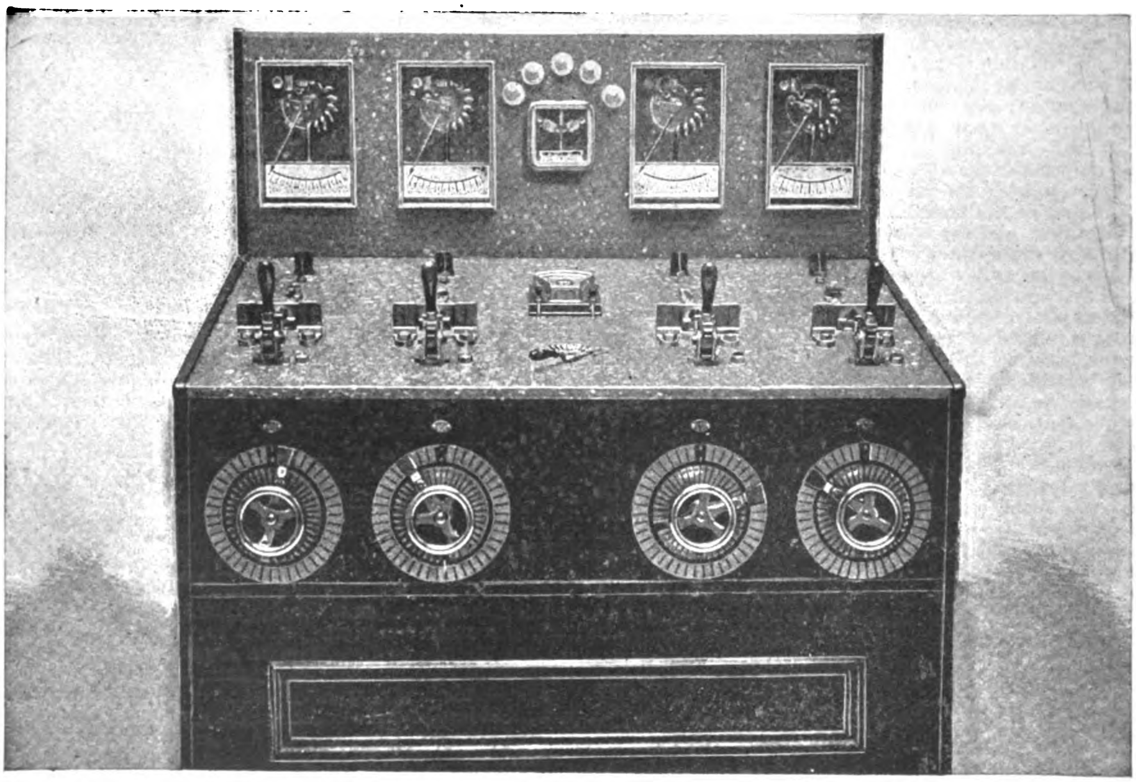
The Ries Electric Specialty Company, of Baltimore, are having such a large demand for the Ries regulating socket for alternating current incandescent lamps, that it has become necessary to increase facilities. In order to meet the demand it was decided at a recent meeting held by the company, to increase its capital stock to $150,000, which, we are informed, was all subscribed before the increased capitalization papers were issued. The company are now making their sockets for all standard lamps and for alternating current circuits of any voltage from 50 to 110. These sockets are also having a very large sale to manufacturers of alternating fan motors, who recommend them highly.

This company have delightful offices at the corner of Eutaw and Baltimore streets, Baltimore, Md., and cordially invite any visitors to their city to make their headquarters with them.

EDISON CONTROLLING TABLE FOR STREET RAILWAY STATIONS.

In the operation of electric railroads not the least point for consideration is that of facility and rapidity of control of the electric power generators. Until recently the large switchboard has been employed necessitating extreme agility on the part of the electrician in charge to bring the output of his generators to the desired point, and this plan has been found not only cumbersome, but expensive.

In order to secure a thorough, effective and rapid control of the generators in an electric railway station, a new device has been gotten up by the Edison General Electric Co. known as the railway controlling table, and shown in the accompanying illustration. On this are mounted all the regulating and indicating apparatus in the most compact and convenient space. The frame work is of strong bar iron. The lower part of the front of the table and the two ends are of sheet iron ornamented with a moulding in relief. The table top, upper part of the front and the upright back-piece are, in the table illustrated, of polished Tennessee marble, but this is an exceptionally fine piece of work; the more frequent custom is to have these pieces made of polished or plain slate. In front are the dynamo field regulators operated by wheel handles and duly numbered in reference to the machines they control. On the table are mounted the crossbar snap switches—new style switches recently designed—the dynamo fuse blocks and the equalizing bar switches, one of each for each dynamo; a voltmeter of the Weston type and a voltmeter switch of the regulation pattern.



Edison Controlling Table for Street Railway Stations.

On the upright back-piece are the amperemeters and the galvanometer. The amperemeters are of the standard Edison type, the solenoid of bar copper highly polished being mounted directly on the marble. The covers are of polished brass with moulded edges in which are set the beveled glass fronts.

The galvanometer shows when the voltage of the current of one of the generators about to be switched into circuit is the same as that from the other machines already supplying the circuit. It consists of two coils arranged one on either side of a pivoted indicating needle of soft iron. This needle is polarized, being pivoted within a piece of steel previously magnetized. If the voltage of the current from the generator ready to switch into the circuit is too high or too low, the deflection of the needle indicates the fact, so that the field regulator can be adjusted until the voltage is correct, when the needle presents no deflection. This instrument is mounted directly on the marble, its cover being similar in style to those of the amperemeters just mentioned.

With this controlling table in the station, the electrician has no difficulty in swiftly regulating his output of current to meet the varying conditions under which the road may be working. With one hand on the snap-switch handle and the other on the wheel of the field regulator an almost simultaneous movement is possible and control is thus immediate. The table shown was designed for four generators.

"THE STREET RAILWAY GAZETTE."

Our readers will be interested to learn that Mr. M. J. Sullivan, the editor of the *Street Railway Gazette*, of Chicago, has now become the proprietor of that journal, and will henceforth continue to conduct it as editor and publisher. We have before us the issue of May 30, which appears in a warm, old-rose cover. The number before us contains an interesting article on "The Future of Electrical Traction," by the sanguine Mr. Erastus Wiman and a variety of other matter, largely electrical, of interest to the street railway manager. The *Gazette*, besides containing each week the news of the street railway world, publishes a divided directory of American street railways showing the four hundred roads already operated by electricity and the four hundred roads laboring under the old system. Mr. Sullivan has our best wishes for his success.

THE ELECTRIC HEAT ALARM AND THE NEW ENGLAND INSURANCE EXCHANGE.

The Electric Heat Alarm Co., whose excellent little device for indicating the presence of hot bearings in all kinds of machinery was recently described in these columns, are justly proud and exultant over the endorsement of their apparatus by that conservative body, the New England Insurance Exchange, as shown in the following letter:

Boston, Mass., June 1, 1892.
New England Insurance Exchange, No. 55 Kilby Street.

Electric Heat Alarm Co.,
No. 113 Devonshire street, Boston Mass.

Gentlemen.—We have carefully examined your system of heat alarm, together with the thermostat used in that connection, and we are of the opinion that this apparatus will prove of value in giving timely warning of heated bearings.

We believe that in all fast-running machinery the installation of this apparatus would not only materially lessen the danger of fire from hot bearings, but would go further and very quickly pay for itself in preventing the destruction of valuable machinery, even when there was no probability of a fire resulting.

We heartily recommend the use of this apparatus to all parties subject to danger from heated bearings, and we believe that with a thoroughly installed system such danger would be reduced to a minimum.

Very truly yours,
C. M. Goddard, Secretary.

THE NEW PORTER & LEAVITT GRAVITY BATTERY FAN.

MORE than a year ago several sizes of neat and efficient small battery motors were placed upon the market by the Porter & Leavitt Electric Motor Company, of Providence, R. I. Notwithstanding the general unreliability of primary batteries and the necessity of their frequent and expensive renewal, many thousands of these little motors have been sold. Those having been fortunate enough to have storage battery current available for these little motors will testify as to what an inexpensive and reliable luxury the Porter & Leavitt fan outfit is.

Quite a number of people in New York City, for instance, have two such outfits—one for their residences run by storage battery and another on the desks in their offices, the storage batteries being rented from the Storage Battery Supply Company. A large number of people, however, cannot conveniently avail themselves of storage battery current, and in the majority of towns where such batteries are not rented as they are in New York, the use of such current would involve quite an initial expense in the purchase of one or two cells of battery.

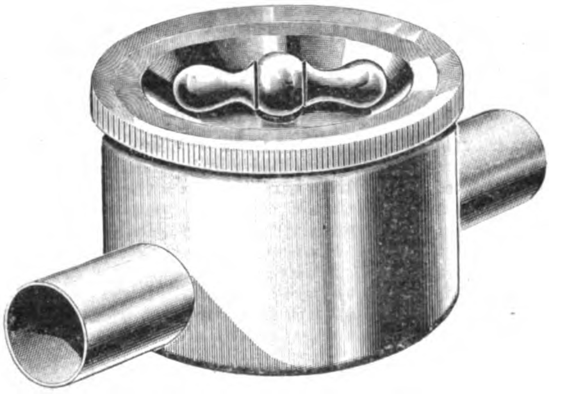
A large number of alleged successful cheap primary batteries have been placed upon the market within the last year or two, the use of which has often proved disappointing. The Porter & Leavitt Co., however, seem to have solved the problem of a primary battery fan outfit, by having succeeded in specially winding a fan motor for service on gravity batteries in groups of two or three. One of their fan outfits, for instance, they run for months, night and day, from six cells of ordinary gravity battery arranged in three pairs, connected in series, each pair being in multiple. The cost of such an arrangement is computed by the company to be 1¼ cent for 24 hours' constant work, although were the cost to be 10 times that much it would not be excessive as compared with the comfort involved.

The new gravity battery motor, the advertisement of which will be found in another part of this paper, is mounted on a polished cherry base, provided with a two-point switch—one point being used when the fan is in motion and the other switching into circuit a resistance of 15 ohms in order that the gravity batteries may not be on a dead open circuit while the fan is idle.

Now that a fan has been devised for the good old reliable gravity battery, the business outlook for the Porter & Leavitt Co. at the beginning of the warm season is particularly bright.

NEW TEN-AMPERE "FLUSH SWITCH."

THE new 10-ampere "Flush Switch" illustrated herewith, is manufactured by the Interior Conduit & Insulation Company of New York, at the suggestion of a prominent architect and is a production which has received high endorsement and commendation from the electrical trade. The engraving shows the many desirable features of the article. A notched cover is indented so as to allow the handle of the switch to be "flush" with the wall on which it is placed and a brass rim extends around the edge so as to protect the wall from soiled hands when unscrewing the cover, and at the same time serving to impart a finish to the switch when placed in position. The advantages of this switch are at once apparent and the article instantly commends itself to the attention of architects and others interested in rendering the various appliances used in conjunction with incandescent electric lighting ornamental and unobtrusive, as well as useful.



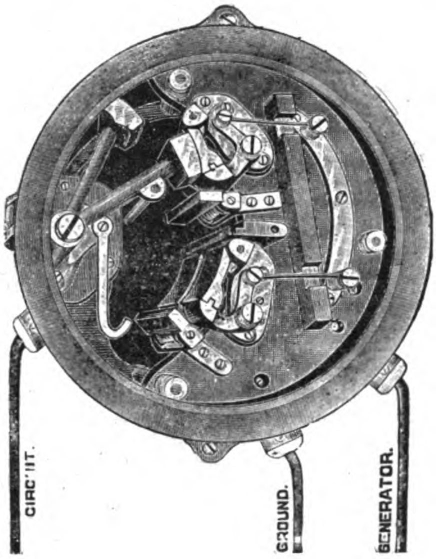
TEN-AMPERE "FLUSH SWITCH."

THE BUCKEYE ELECTRIC CO.

THE BUCKEYE ELECTRIC COMPANY are putting on the market a new double-coil filament 32 c. p. lamp. The effect is magnificent. Business at both Chicago and Cleveland continues good.

THE UTICA QUADRUPLEX LIGHTNING ARRESTER.

THE cut below shows the Utica quadruplex lightning arrester, made by the Utica Electrical Mfg. & Supply Co., of Utica, N. Y. It is similar in construction to their simplex and duplex arresters, and is designed for street railway, light and power plants—where the old adage "that lightning never strikes twice in the same place" will not hold good. The lightning arrester here shown will take care of four lightning bolts in succession before requiring attention, and all the damage lightning can do is the melting of a fuse wire which can be readily replaced. The contacts are made of bronze metal and very heavy—mounted on slate, enclosed in water-tight iron case, the case being provided with porcelain bushings for the entrance of wires. There being no magnets used in this arrester, it is equally suitable for either alternating or direct currents of any voltage and ampereage.



UTICA QUADRUPLEX LIGHTNING ARRESTER.

THE WADDELL-ENTZ COMPANY.

THE WADDELL-ENTZ ELECTRIC CO., whose apparatus is well known to our readers, has sold all its rights and ceded its entire business to a new organization called the Waddell-Entz Company. The latter company has just taken up its quarters on the fifth floor of the new *Mail and Express* Building, at 203 Broadway, this city, and has already begun to enlarge its facilities for manufacturing the Waddell-Entz apparatus.

NEW YORK NOTES.

THE C. & C. ELECTRIC MOTOR CO., of 402 and 404 Greenwich street, have always been noted for the finish and excellence of their catalogues, and the last one just to hand is a beautiful production well worthy of the Bartlett Press, whose imprint it bears. It is in point of fact more elaborate than anything hitherto put forth by the C. & C. Electric Company, and may be said to mark a further stage of progress in the development of their large and expanding business. It includes not only a list of their motor and dynamos, but gives a careful description of all the supplies necessary for the complete equipment of electric light and power plants. Among these may be specially mentioned their own switches, while there are such specialties as their fans, blowers and other ventilating machines; automatic motor starting boxes, organ rheostats and organ attachments. The company of late have sold a large number of their standard generators. This part of their business has of late assumed large proportions, and already begins to rival, if not exceed, the motor output. Once or twice lately we have had occasion to illustrate power plants in which C. & C. generators were not less conspicuous than the C. & C. motors.

THE increasing business of the Rose Electric Light Supply Company, of St. Louis, has necessitated their opening a New York office. This office is located in room 232 of the Electrical Exchange Building, under the management of Mr. H. F. Gray. Mr. Gray will be glad to receive correspondence or calls from those who are desirous of purchasing second-hand electrical apparatus in first-class condition and is prepared to fill orders promptly. There has long been a necessity in New York City for a first-class house carrying a large stock of second-hand dynamos, motors, etc., and we believe the success of Mr. Gray and his New York office is assured.

Mr. Edward P. Thompson, New York, started nine years ago to test the practicability of establishing a successful business as a specialist in soliciting U. S. and foreign patents for *electrical* inventions. That this has been possible is illustrated by the fact that during the past month he has had entrusted to his care twenty-nine *electrical* foreign patent cases besides the usual numbes of U. S. electrical cases.

The Premier Electric Co., 17 and 19 Whipple street, Brooklyn, have now issued to the trade a circular as to their basic patent, 321,049, controlling the type of motor that they make. It will be remembered that an open letter of theirs on this subject was recently published in these columns. This circular amplifies and enforces the statements then made. Their motors of the three-pole armature type are known as the "Premier" or the "Challenge."

Mr. J. G. Bishop, late electrical expert with the J. A. Roebling Sons Co., has now joined the forces of the Safety Insulated Wire Co., of this city. Mr. Bishop's experience in the manufacture of insulated wires will no doubt make him a valuable addition to the staff of the Safety Co.

Mr. P. C. Burns, manager of the Peru Porcelain Works who recently spent some days in this city has returned West. He was well satisfied with his trip to the metropolis.

PHILADELPHIA NOTES.

Messrs. Queen & Co. are just issuing a revised price list of their "Magnetic Vane" ammeters and voltmeters, in which two forms are given, one with brass and the other with iron cases. The difference in price is occasioned only by a corresponding difference in material used and external finish, for both types are calibrated to the same degree of accuracy.

These instruments are extensively employed for switchboard purposes, and enjoy an excellent reputation. As decided changes in appearance and prices have been made it will be well for interested parties to obtain a copy of the special descriptive circular No. 330.

The Heisler Electric Co. are installing plants of their long-distance series incandescent lighting apparatus in the towns of Greenport, L. I.; Cartersville, Ill.: San Rafael, Cal , and at points in Montana and Mexico. The Heisler Co. have recently introduced some new and attractive designs in incandescent lamps for decorative purposes. These lamps are blown from colored glass, and are made in any candle power or for any current from 4 to 10 amperes and to fit any standard socket. Orders for these lamps have already been received from Mexico, Central America and Italy.

Messrs. Pepper & Register are installing a 1,500-light storage battery plant in the building of the American Fire Insurance Co., a 150-light storage battery plant in the house of Mitchell Harrison, of Chestnut Hill, and a 500-light plant in the house of Gen. E. Bird Grubb, of Edgewater Park, N. J.

Messrs. Schultz and Gaylord, of the Pennsylvania Electric Engineering Co., have just returned from an extended business trip through New England and the West. They report large sales of their Pennsylvania lamp.

Mr. M. S. Shapleigh has resigned his position as agent for the Electrical Supply Co., and will hereafter act as manufacturers' agent and jobber of general electrical supplies at his old address 244 Arch street.

Mr. T. L. Townsend returned last week from a most successful trip through New England and Southwestern Canada.

WESTERN NOTES.

Mr. W. F. Matteson, who for so long past has been connected with Wm. Hood, the dealer in specialties at 239 La Salle St. as electrician, has resigned and accepted a position with the Patton Motor Manufacturing Co. and will leave shortly for Denver, Col., to look after the equipment furnished by that company to the street railway company there. Mr. Matteson is a bright young electrician and with his energetic and pushing qualities is well fitted for the new line of work he has undertaken.

The Electric Appliance Company report large sales of Meston alternating current fan motors. Although the season can hardly be said to have opened up, they are nevertheless considerably behind on their orders already and have had a demand far in excess of their expectations. The demand for "Canvas Jacket" wire is also very heavy and they are falling behind on orders, as the factory is crowded to its utmost capacity.

The Buckeye Electric Co. are having a good demand for their Buckeye coiled filament lamp for central stations and electric street railways, and the Chicago office, under the able management of Mr. J. H. Cooke, is securing a large number of such orders.

The Central Electric Company are putting on the market a very compact little fan motor, made in sizes 1/6, 1/8 and 1/4 h. p. These motors can be used on desks, and can be attached to the wall by a simple device, the whole being the product of the Interior Conduit & Insulation Company, for which the Central Electric Company are general Western agents. The price asked is a modest one, and they should command a ready sale. Mr. William H. McKinlock, president of the Central Electric Company, has just returned from New York. Dr. John McKinlock of the Central Electric Company has recently been confined to his house by sickness, but is again at his desk.

The Standard Railway Supply Co., Chicago, have opened handsome offices at suite 1117 Monadnock Building, and will deal in mechanical railway specialties. Mr. G. Meyers, well known in street railway circles, is the manager of the new concern.

Mr. Geo. Westinghouse, Jr., has succeeded in getting his World's Fair lighting bond reduced to $500,000, provided he can give one with two names to it.

Messrs. J. W. Godfrey, general manager, and Augustus Noll, electrical engineer, of the New York Insulated Wire Co., were Chicago visitors last week.

NEW ENGLAND NOTES.

Swan & Lane, have become associated as electrical contractors and have commenced business with headquarters at 194 Summer street, Boston. They will do a general electrical construction business, but will devote their time specially to the installation of isolated plants, and all kinds of wiring. Mr. Swan has had a large and varied experience in the electrical business, is full of energy, and popular with all who know him, having last been connected with the Boston Electric Light Company, as superintendent of the incandescent department. Mr. Lane has also had a varied experience, both in mechanical and in electrical engineering, having been connected with the Union Switch and Signal Company, of Pittsburgh, latter with Lane & Melcher, and lastly with Swan & Small who did all kinds of general electric work, in the manufacture and repair of dynamos, lamps, motors, etc., and general mechanical goods. With their past experience Messrs. Swan & Lane, ought to enjoy a large patronage, and will doubtless keep up the high record which they have already achieved.

The Jarvis Engineering Company, of Boston, have closed a contract with the Newport Illuminating Company of Newport, R. I., for six Armington and Sims compound condensing engines, for their new station. The sizes of the engines are as follows: Three engines, 12 inches and 18 inches diameter by 12 inches stroke; one 15¼ inches and 25 inches dyameter by 15 inches stroke; one 15 inches and 23 inches by 15 inches stroke, and one 13 inches and 20½ inches by 15 inches stroke. The station, which is to be erected on the old Richmond Mill property, will contain about 1,000 h. p. in engines, and three Climax boilers have been ordered from New York. The Jarvis Company will build all the foundations for the engines, and dynamos, and will raise the building considerably, and will do the complete carpenter work. The Jarvis Company been also closed a contract for the Worcester and Millbury Street Railway Company's new power station. This contract will comprise two new type tandem horizontal compound engines, of about 250 h. p. each, the boiler setting and complete foundations.

The Davidson Ventilating Fan Company, of Boston, have removed to more convenient and more commodious quarters on the second floor of 34 Oliver street, where they will have much more room to attend to their rapidly increasing business. They have just completed a ventilating system for the Boston Music Hall, which will secure comfort and fresh air to the patrons of the popular concerts at that establishment during the hot summer months They are also engaged in installing a ventilating plant in the Globe Theatre of this city, the order for which was given by Dixey for use during his engagement in "Iolanthe."

Samson Cordage Works.—This concern, of 115 Congress street, Boston, has been increasing its plant for the manufacture of "Samson" arc light cord and trolley cord. It has reached the limit of capacity with its present water-power, and to avoid the use of more steam it has purchased a water-power in the neighborhood of its factory, proposing to transmit the energy by electricity.

Drake, Payson & Whittier, of Providence, have a few "facts" which they can prove, and which they would like to impress on every user of electric light in New England. Send for a copy of them, as they are quite interesting.

Electrical Engineer.

VOL. XIII. JUNE 22, 1892. No. 216.

MODERN AMERICAN TELEGRAPHIC APPARATUS.—III.

BY

F. W. Jones

QUADRUPLEX APPARATUS.

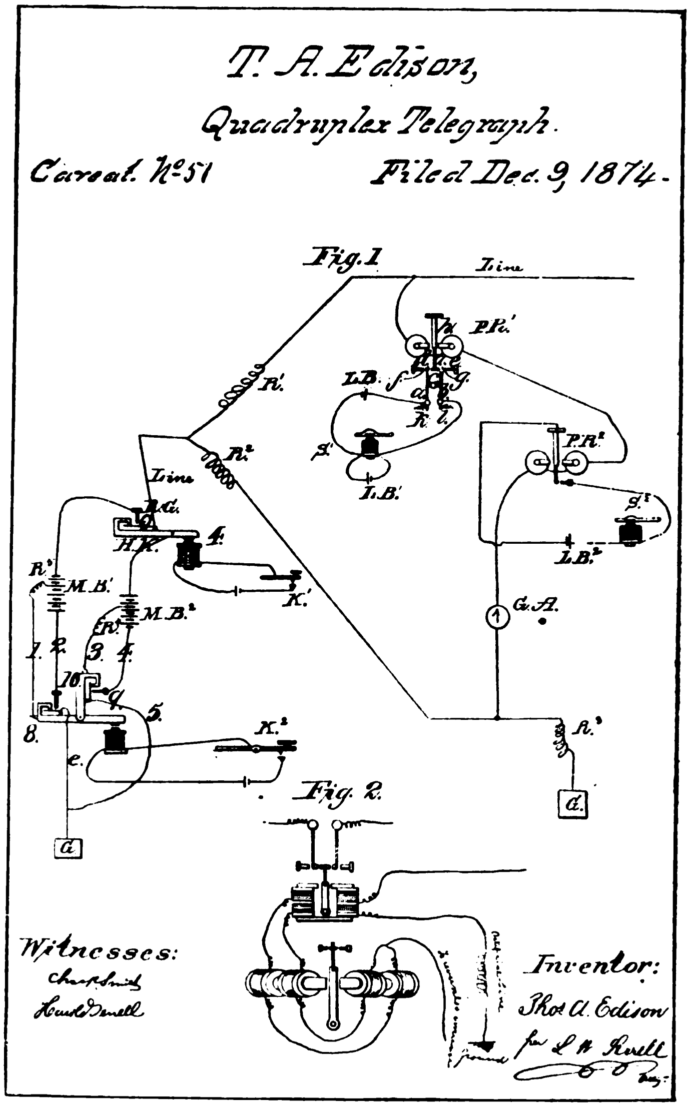
IN the *Journal* of Dr. P. Wilhelm Brix, Vol. II, page 224, published in Berlin in October, 1855, Stark of Vienna, after describing his system for transmitting *two* messages simultaneously in the same direction on one wire, he says that "with the method of double transmission in the same direction we may also combine that of *counter-transmission*, and hence arises the possibility of simultaneously exchanging *four* messages upon one wire between stations." Several European electricians worked at the problem but did not succeed in securing a satisfactory transmission of two messages in one direction.

A system very similar to the one introduced by Edison in 1874, was described by its inventor Dr. Schrader, of Vienna, in Brix's *Journal* Vol. VII, page 85, April, 1861. Schrader used two relays, one having two armatures (polarized) and the other one a neutral armature. He also used continuity-preserving keys.

The serious defect or "bug" in his system was the break or false signal in the circuit of the sounder of the neutral relay when the armature of the polarized relay was changing from back to front contact. A similar difficulty proved a bête noir in the Edison system, and still exists, defying an entire removal, although Edison and others have done much to counteract its detrimental effect in signaling; so that now the system very successfully accomplishes four transmissions twelve hundred miles with two automatic repeaters dividing the wire (160 lbs. copper per mile) into three approximately equal circuits. Or one thousand miles on a wire (210 lbs. copper per mile) divided by one repeater into two circuits.

One of the most ingenious devices for overcoming the defect already alluded to, is a compound polarized relay shown in Edison caveat No. 51, filed in the Patent Office December 9, 1874, a fac-simile of which is shown in Fig. 1. It is described in the caveat as follows: "In Fig. 1 of diagram P R′ is a polarized relay worked by increased and decreased currents. The tongue *h* is held equidistant from the points *d*, *e*, by the two arms *a*, *b*, which arms are held against *c* by their spiral springs *k l*. These arms have platina points *g f* and the tongue *h* when the weaker battery which works the other polarized relay P R² is sent, remains centred by the arms *a*, *b*, because the power of the magnet is insufficient to overcome the spiral springs *k l*. When thus centred, the platina point of the tongue is in contact with both the platina points on the lever *a b* and the local circuit of the sounder is closed but the sounder itself is not closed because it is placed in a bridge wire or a balance of batteries."

"Supposing the double-lever sounder at the distant station is closed the main battery is increased several times in strength. This increased current coming [going] over the line and passing through the polarized relay P R is sufficient to overcome the springs *k*, *l*, and the tongue goes to the right or left according to the polarity of the current, say to the left. In doing so the local circuit is broken between the tongue and lever *b* allowing the battery L B² to close the sounder. The tongue being to the left and the sounder closed and the operator at the distant [station] should commence signaling to the relay P R² by reversing the battery, then the tongue *h* would fly from one side to the other at every reversal, but the local circuit will not be closed, for just as the tongue *h* comes in contact with the lever *b* it leaves *a*, thus keeping the local open and the



FIGS. 1 AND 2.—EDISON'S CAVEAT OF 1874.

sounder closed, so it is obvious that although the effect of the reversals is to constantly work the tongue of P R^2 it will produce no effect on the sounder, which is essential for obtaining perfect signals. M B^1 and M B^2 are the two main batteries, say, of 100 cells each; M B^1 has zinc to line; M B^2 has copper to line."

Fig. 1 in diagram shows a bridge and Fig. 2 a differential arrangement; the other references will be readily understood by inspection.

The quadruplex had been put in operation, prior to the date of this caveat, by Edison between New York and Boston 240 miles with two single-wound relays, (one polarized and one neutral) on the bridge plan, with what is well known as Edison's "bug trap;" that is, one up-stroke repeating sounder working from the back contacts of the neutral relay, and by its up contacts actuating an ordinary sounder. The bridge system was adopted by the Western Union Telegraph Co. also for longer wires, as it was thought the effects of static induction could be better compensated.[1]

Edison had placed a condenser around the neutral relay in the bridge to hold its armature steady during the reversal of the distant main battery.[2] In August, 1875, I found that a condenser could be applied to differentially wound relays to steady the neutral relay, and the first circuit on this plan went into operation between Chicago and Buffalo with a repeater at Detroit.[3] In April, 1876, Mr. G. B Prescott, who at that time was electrician of the Western Union Telegraph Co., applied for a patent issued May 15, 1877, applying the condenser to an independent electromagnet acting independently but in conjunction with the neutral relay magnet upon an extension of its lever in the bridge system.[4] In 1876, Mr. Prescott's relay was superseded by a compound polarized relay identical in principle and operation with P R^2 shown in Edison's caveat and shown in Prescott's work, page 849, and described by him as one of several important modifications by Messrs. George B. Prescott and Gerritt Smith, and also described and claimed by Mr. Smith in his patent No. 185,589, Dec. 19, 1876, (one-half assigned to G. B. Prescott). This relay had very extensive use and when carefully balanced and adjusted, aided by Edison's bug trap and condenser gave better signals than had hitherto been obtained upon the neutral, or No. 2 relay, as it is known in telegraph circles.

Owing to the difficulty of maintaining this relay in working adjustment the Western Union Telegraph Company shortly after adopted the general use of the differential system substantially as first put up between Chicago and Buffalo. Mr. Gerritt Smith afterwards modified Mr. Prescott's bridge relay having an independent magnet for condenser, by winding an extra or third coil upon the differential neutral relay and discharging the condenser through this coil, at the same time introducing resistance between the relay and earth so that the condenser would be charged to a higher potential. It is this system that has recently undergone another change in the displacement of the Gerritt Smith arrangement by the Frier relay described in THE ELECTRICAL ENGINEER, May 4, 1892, page 454.

In 1885, I arranged for the Postal Telegraph-Cable Co., the following system which is worked on wires of all kinds and lengths and has received the unqualified approval of the managers and chief operators.

In Fig. 3, D, D^1, D^2, D^3 represent four compound shunt-wound dynamos. Two of these dynamos are of low potential (one plus and one minus) and two are of high potential (one plus and one minus), and they are connected to a new style of pole-changer, marked P C, through a four-button switch S W.

P C makes four contacts, 1 and 3, when it opens, and 2 and 4 when it closes Contacts 1 and 2 are adjustable springs and continuity preserving, as the end S of the lever of P C moves up or down. The contacts 3 and 4 are fixed, and a space occurs when the end L of P C moves from one to the other. The ends of lever L and S are insulated by *i* from one another. It will be seen that the dynamos are connected as follows: One hundred minus to contact 1, one hundred plus to contact 2, three hundred minus to contact 3, three hundred plus to contact 4. Two wires lead from P C to an improved form of single transmitter S T. One wire connects L with contact point C, the other wire connects S with the lever L^1. The spring *y* of S T connects through a three-point switch, and a regulating resistance R with the dividing point of the relay N. P R is a polarized relay, and I C is an induction coil having three windings of one hundred ohms each. Two of these windings are included in the main and artificial circuits in the usual differential manner. The third winding is connected with the third electromagnet, marked M^2, of the relay N.

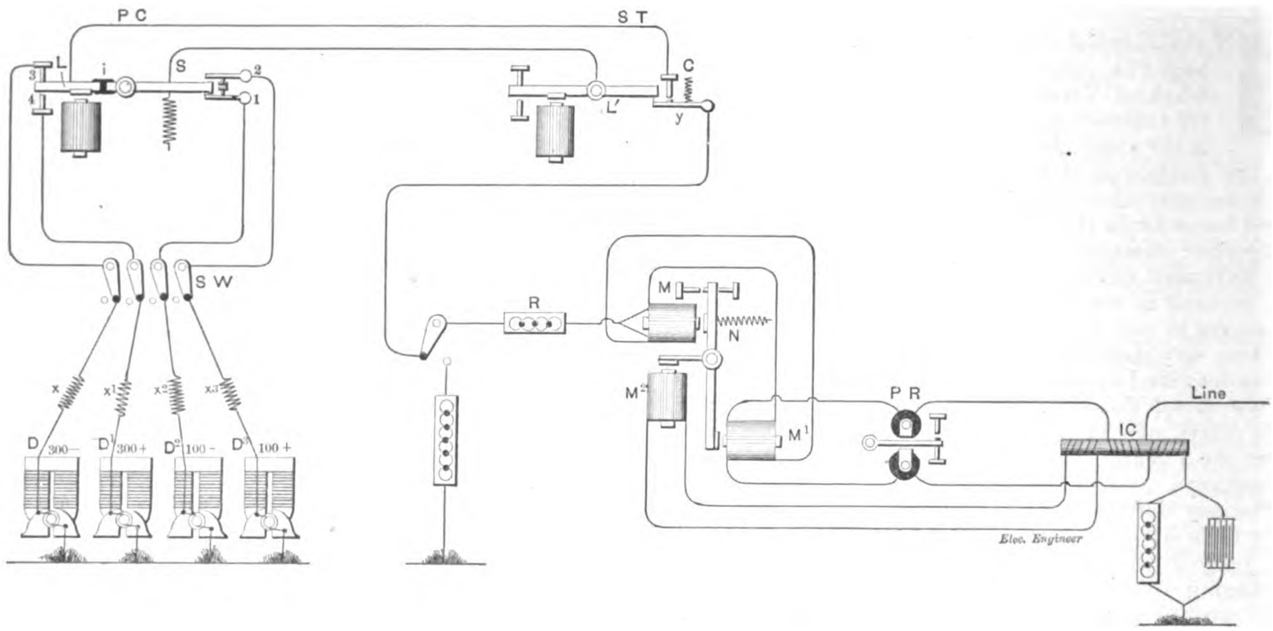


FIG. 3.—JONES DYNAMO QUAD AS EMPLOYED BY THE POSTAL TELEGRAPH-CABLE CO.

---

1. See Prescott's "Electricity and Electric Telegraph," page 835.
2. Ibid, page 841.
3. Patent No. 191,439, May 29, 1877; also *Journal* Am Elec. Soc. *Vol. I.*, p. 26.
4. Prescott. "Electricity and Electric Telegraph," page 839.

The electromagnet M and M^1 are in series differentially in the line and artificial circuits, the total resistance of both magnets in either circuit being about 300 ohms. The polar relay P R shown in perspective in Fig. 4, has the usual resistance of 400 ohms in each winding.

The resistance R between the three-point switch and N is for the purpose of reducing the potential of the dynamos when it is desired to work a line circuit of shorter length than is designed for the normal potential of the machine. Thus from the same dynamos several quadruplex circuits of varying lengths or resistances may be worked, provided the normal potentials of the machine are adapted to the circuit of highest resistance. The diminution caused to the incoming current by the insertion of R is counterbalanced on the relays largely by the greater quantity of the incoming current that will go to earth *via* the artificial circuit, thus traversing two sets of relay convolutions.

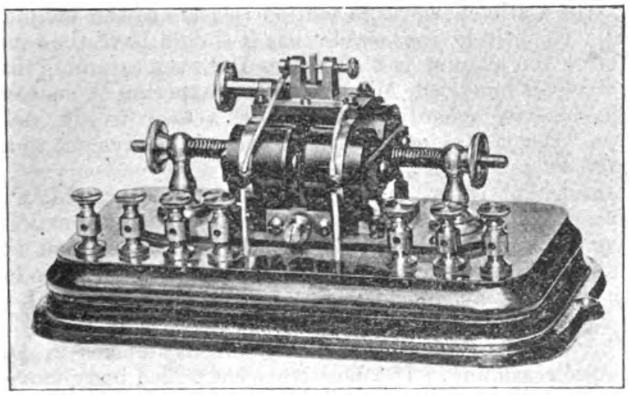

FIG. 4.—JONES POLAR RELAY.

Number 2 relay, N, is shown on a large scale in Fig. 5. A and A^1 are the differential main line electromagnets connected up in series. B is the electromagnet through which the secondary circuit of the reversal coil I C, Fig. 3, is connected. The lever of the relay is made of aluminum and carefully counterbalanced by giving the armature lever of A^1 an angular shape. A brief inspection of Fig. 3 will show that the outgoing currents passing differentially around the reversal coil I C produce no effect upon the third winding connected with magnet M^2. The incoming signaling current, however, during its approach and retreat sets up in the secondary coil of I C induced currents which momentarily energize electromagnet M^2 which holds the lever of the relay in opposition to the force of the retractile spring. Following is a table of inductance and time constants of some of the instruments alluded to :

Name of Relay.	1. Coil resistance. Ohms.	Distance of armature from cores. Mils.	Continuous current. Milliamperes.	Inductance. Henrys.	Time constant. Seconds.
G. Smith, 3 coil	306	4.	6.5	1.157	.0037
Frier, self-polarizing	395	4.	6.5	2.131	.0054
Jones, triple magnet	293	4.	6.5	1.583	.0050
Reversal coil, primary	100	40.	6.5	0.464	.0046

In any circuit the whole self-induction is equal to the sum of the inductance of all its parts. A quadruplexed circuit of the Postal Telegraph-Cable Co., including 390 miles of copper line wire, with an inductance of 2.53 henrys, with 60 milliamperes of current, and a time constant of .0029 second, also includes the coils of six instruments, which have an aggregate inductance of 6.71 henrys, with a current of 6½ milliamperes. The time constant of this wire and apparatus, so far as inductance is concerned, is .0037 second, and this may be reduced by increasing the resistance of the circuit without adding to its inductance. The time consumed in this circuit by the sending station's currents rising to 0.634 of their final value in the coils of the three instruments at the receiving end, so far as inductance alone is involved, is approximately .0014 second, allowing 1,000 ohms inductionless resistance in the dynamos at each end, and 880 ohms in the line wire. It will be noted that the three line coils of the sending station's apparatus are inductionless to outgoing currents. The advantage of the triple-magnet form of relay, shown in Fig. 5, becomes apparent, as the time constant of the main relay coils in series is no greater than the time constant of either of these coils separately; but to attempt to maintain the same magnetic effect by placing the convolutions all on one set of cores would be to increase the inductance which is proportional to the square of the number of turns included in one bobbin.

The retardation due to the electrostatic capacity of the line wire is most seriously felt upon all long circuits, and seems to be the greatest cause of mutilation of signals upon the No. 2 relay.[1] Iron wires do not charge and discharge so quickly as copper wires. To entirely remove inductance from a relay is to render it incapable of exerting any magnetic pull, so that all relays must be adapted to the work they are required to perform, just as a strong clumsy horse is selected for the dray and a fleet nimble one for the race-track.

Besides the inductance and retardation alluded to, there is also a possibility of the pole-changing transmitter, such as illustrated on page 454 of THE ELECTRICAL ENGINEER, of May 4, and also in Fig. 3 of this article, marked P C, having their points opened so wide that the time consumed by the lever in crossing to reverse the current will exceed the time the circuit requires to fall to zero.

In the case of the system shown in Fig. 3 the relays have been designed to utilize the signaling current as much as possible for magnetic effect, and at the same time to possess the least mechanical and electromagnetic inertia. It is true that an additional resistance and inductance have been added to the circuit by the primary coil of the reversal coil I C to the extent of 100 ohms and .46 henry, but

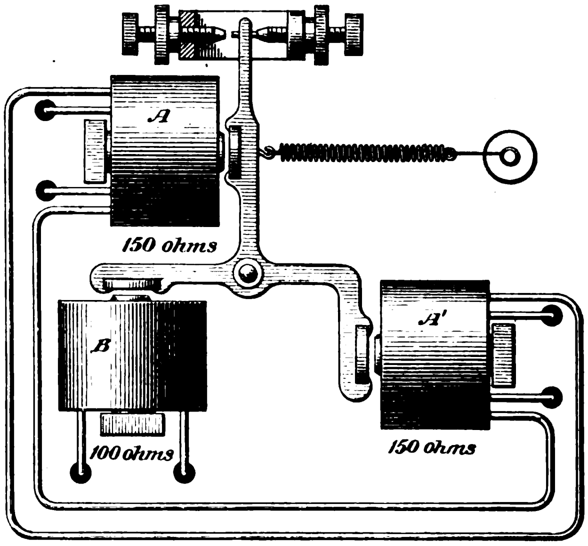

FIG. 5.—JONES QUAD TRIPLE MAGNET NO. 2 RELAY.

---

[1] See Preece and Sivewright, "Telegraphy," (1891 edition, page 160).

in practice it is found that the important service of this coil in steadying the tongue of the relay during the interval of no magnetism is so great as to render entirely unimportant such additional inductance. With the admirable bug trap of Edison this system has worked a direct wire between New York and Chicago without repeater for a long period. It is obvious that a relay, otherwise well designed electrically for the work required of it, may be handicapped by mechanical inertia.

As I am an interested party in some of the apparatus described, and am anxious to place before the readers of the ENGINEER facts not hammered entirely upon my own anvil, I submitted the new and ingenious relay of Mr. Frier, and the Jones triple-magnet No. 2 relay, referred to in the preceding table, to Assistant Manager Shirley, of the Postal Telegraph-Cable Co.'s New York main office, with the request that a strictly first-class operator give them a trial, which was made upon the New York and Pittsburgh circuit, 470 miles, under the supervision of Mr. Minor M. Davis. Mr. S. W. Churchill was assigned to the test, the circuit being in full operation, and nothing was known by him of the names or inventors of the two relays. His report is as follows:

> F. W. JONES, Chief Electrician.
>
> *Dear Sir.*—In accordance with your request, I will give you my opinion concerning the practical working of the instruments which were tested on the Pittsburgh quadruplex, this morning. I have no hesitation in saying that in my opinion the one tried last, or the larger, double-decked relay, worked decidedly better than the smaller, or low relay. In the case of the smaller one, the sending came droppy and uneven, and although it was possible to receive the matter sent (special matter), it would be difficult, if not unsafe, to receive commercial or cable messages.
>
> When receiving from the larger relay there was no dropping or unevenness, and although the sending was much more rapid than when trying the smaller relay, every dot came clearly and distinctly, making it as easy to receive as though it were the first side of a quadruplex. In a long experience as an operator I never worked on the second side of a quad where the sending came clearer or better.
>
> S. W. CHURCHILL,
> Operator.
>
> 187 BROADWAY, NEW YORK, April 27, 1892.

This was the only means at my command to secure an impartial comparative test. In each case the Edison bug trap was used in the usual way. I gave no figures of merit in the foregoing table of measurements because none are possible; it requires actual operation to develop both mechanical and electrical qualities.

The test, of course, is open to a suspicion of having occurred in too friendly an atmosphere; yet it is a starting point for one that will be more conclusive to your readers.

DR. JACQUES' EXPERIMENT ON THE NATURE OF THE ELECTRIC CURRENT.

BY

Townsend Wolcott.

THE experiment of Dr. Jacques[1] seems to have created quite a sensation, and to be regarded as very remarkable, at least by some. In the humble opinion of the writer the most remarkable thing about it is that a man of sufficient intelligence to conceive and carry out such an experiment should think that he is following Maxwell's reasoning when he makes an "ether current" equal, or in any way equivalent to an electric current.

Maxwell distinctly states in article 769, from which Dr. Jacques obtained the foundation of his experiment: "This moving electrified surface will be equivalent to an electric current sheet." That is, the moving statically electrified surface is equivalent to an electric current, and not to the ether through which the surface may be conceived to be passing. Maxwell makes no mention of ether as it is not necessary to his reasoning.

Personally, I do not think Maxwell's experiment would succeed even if it were possible to try it, as the four things involved, (two surfaces and a static charge on each) are fixed with regard to each other; there is absolutely no relative motion. In the next experiment suggested by Maxwell, and which was successfully tried by Prof. Rowland, the static charge is in motion relative to the magnet, and it is entirely reasonable that it should have the same effect on the magnet as a current. But even assuming that Dr. Jacques has tried Maxwell's first experiment successfully, he has, according to Maxwell's own words, only shown "that a moving electrified body is equivalent to an electric current."

I think that if Dr. Jacques' disciple, Mr. Berthold, will carefully read the *words* Maxwell has written in articles 769 and 770, without reading *ether currents* between the lines, he will see that these two experiments are intended to prove the same thing as pointed out in the editorial in the ENGINEER of May 18.

There are several other trifling inconsistencies in Dr. Jacques' reasoning. If a positively electrified body moved in a given direction is equivalent to an electric current in that direction, then a negatively electrified body moved in the same direction is equivalent to a current in the opposite direction. Therefore, when his plates were oppositely electrified, the electrostatic attraction ought to be diminished by the electromagnetic action, if there were any, as the latter would be repellent. This is a somewhat damaging fact, as the deflections which Dr. Jacques expected to get, and which he thinks he did get, depend upon the repulsion of similarly electrified plates being diminished, and the attraction of similarly electrified plates being increased. Again, even granting that the constellation Hercules is stationary absolutely, it does not follow, of necessity, that the ether (if there be such a thing) is stationary relative to Hercules. Moreover, if an electric current be an ether current, a static electric charge is a charge of ether (which, by the way, necessitates a revival of either the one-fluid or the two-fluid theory of electricity); and the Doctor first charged his plates with ether and then moved them through the ether. This proceeding on the part of the learned experimenter bears a strong analogy to the action of the bear hunter, who, by some mischance, became the bear hunted, and who escaped from his infuriated pursuer by first crawling into a hole and then pulling the hole in after him.

Why, may I ask the Doctor, does not the tremendous ether current which is rushing past our globe manifest itself in ordinary electromagnetic phenomena, rendering unnecessary his ether-charged plates? Perhaps it does. Perhaps it is the cause of terrestrial magnetism, and as he has not yet stated whether the direction of the ether current agrees with what is known by the ordinary convention as the direction of the positive current, or the reverse, his best plan would be to study out the direction necessary to make it account for terrestrial magnetism, and another great discovery will reward his diligence.

THE BEST FREQUENCY FOR ALTERNATING CURRENTS.

HAVING regard to all the circumstances of the case, says *Industries*, we believe the American frequency of 130 is about the right one, and that low limits, such as 40 or 60, are a mistake. Recently we have seen 20 periods per second proposed. This would be ruinous both to the pocket and to the eyesight. Helmholtz found that the eye could distinguish 25 periods per second. This low frequency would probably be unworkable in the dynamos and motors, and especially in the transformers.

---

[1] See THE ELECTRICAL ENGINEER, May 18, 1892, "What Electricity Is."

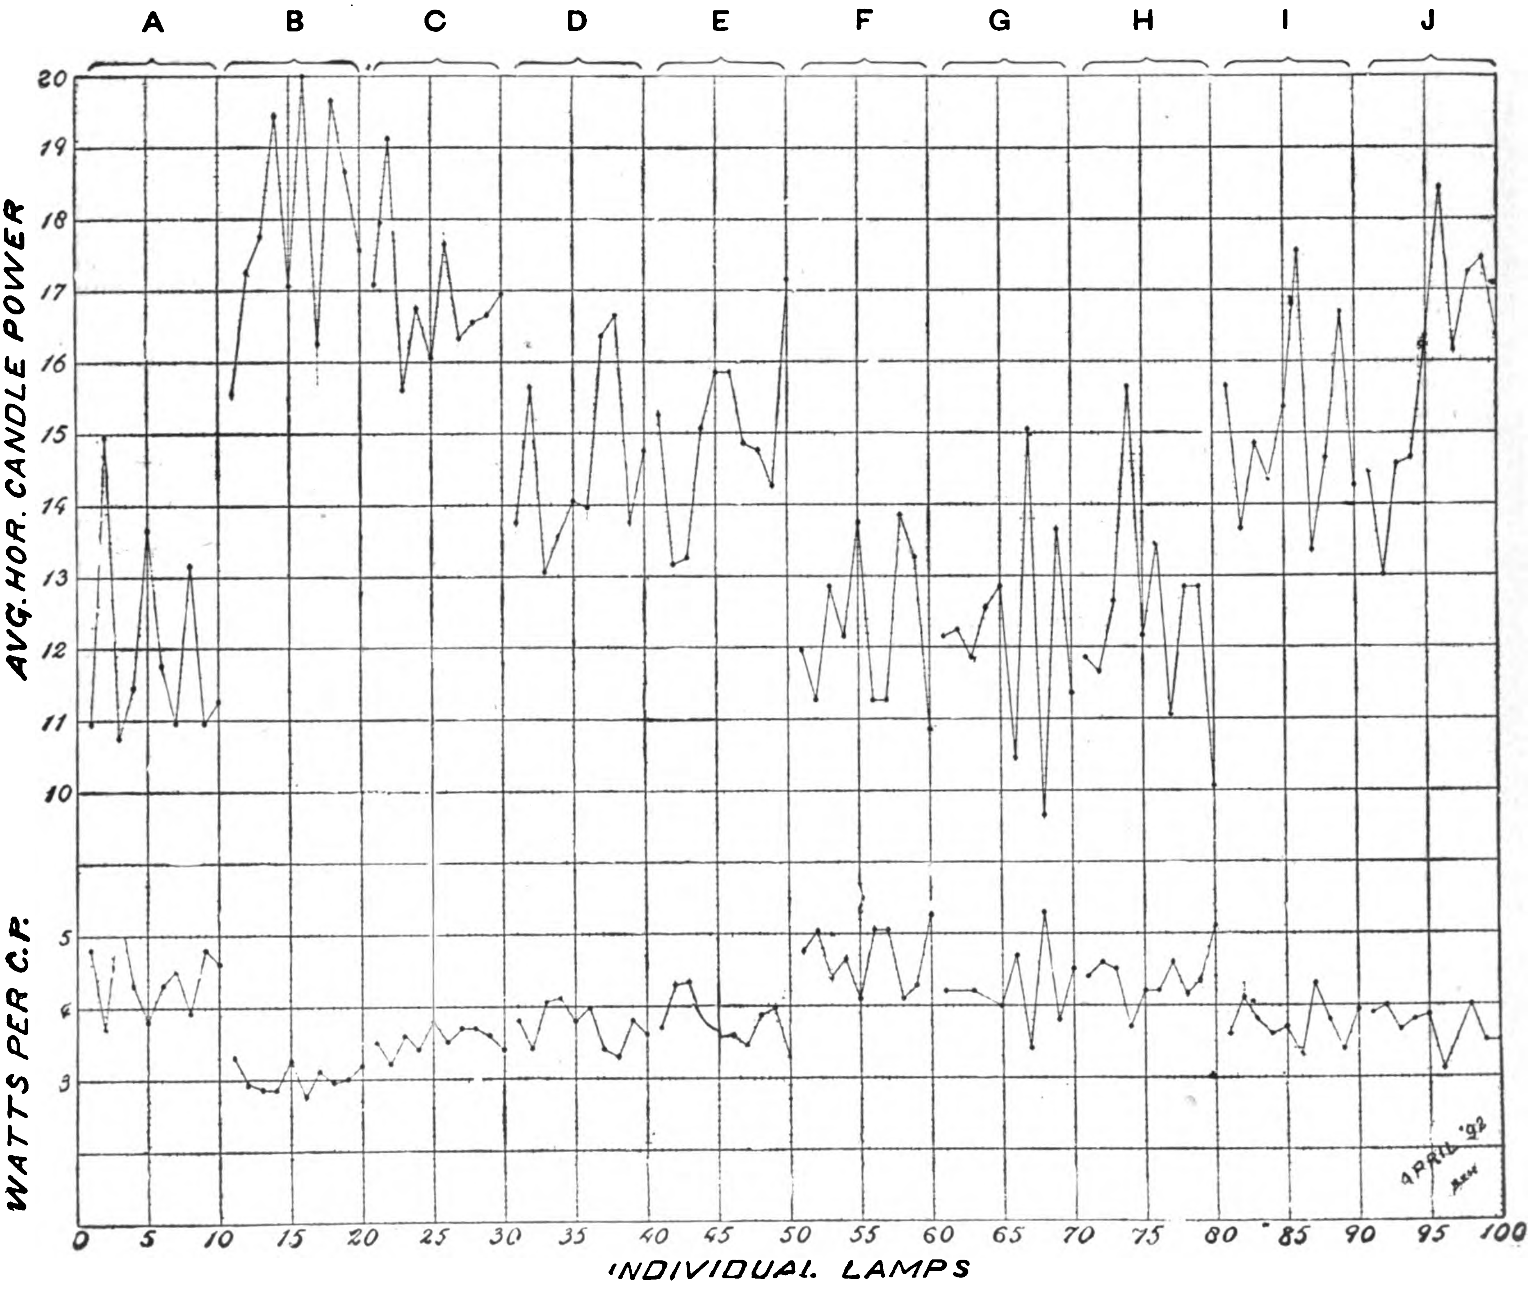
THE COMMERCIAL RATING OF INCANDESCENT LAMPS.

BY

Charles Wirt

The accompanying diagram shows simply what the market affords in the case of incandescent lamps, so far as may be gathered from results which do not include the life history of the specimens tested. The test was undertaken merely to get a fair idea of the character of the output which has now become the product of a large number of factories.

For the purpose of the test lamps were obtained from sixteen different makers. These were bought in the ordinary way of business and there is no reason to suppose that any of the specimens are better or worse than the ordinary run of their kind. Of the lamps so bought, ten of each of ten kinds were tested. All the lamps tested are represented in the diagram, for which the following explanation will be sufficient: Numbers at the bottom refer to the individual numbers marked on the lamps before the test. In the vertical line referring to each lamp are two points, one indicating the watts per candle by reference to the scale and the one above indicating the average horizontal candle-power when the lamp was burned at the volts for which it was marked. The first ten numbers represent lamps of one make, and so with each series of ten. The lines connecting the points are to show clearly which points belong to one set and have no other significance.



Commercial Rating of Incandescent Lamps.

The tests were all made in the photometer-room of the Electrical Supply Co., at 104 Michigan avenue, Chicago. The photometer used had a scale length of 200 centimetres, and was provided with a Methven gas standard by Alex. Wright. When first used a few months ago this standard was checked by measurement of incandescent lamps obtained for that purpose from Prof. Nichols, of Cornell, and by comparison with standard candles, both these checks showing the gas standard to be correct within the limits of observational error. The scale of the photometer was marked to read candles direct, and the spot was capable of being read to about $\frac{1}{10}$ candle at 16 C. P., when the observer's eyes are in good condition for work. To get the average horizontal C. P., the lamp socket was revolved about 600 times per minute by a motor which was placed at a distance and connected to the spindle by a light belt to avoid any vibration of the photometer. Sliding contacts are of course necessary to the lamp socket, and these consisted of the conical step at the lower end of the spindle, and of a double bronze spring, bearing on a brass ferrule below the socket. The loss at these contacts was measured while running with the usual current, and was found to be less than $\frac{1}{1000}$ volt; too small to consider. The results of the rotation of the lamp are in every way satisfactory. It has been the writer's observation that to get the average horizontal illumination in any other way a large number of separate measurements must be made, as the effect at different angles is erratic, due apparently to reflection from the inner surface of the glass as much as to the carbon shadow.

All the lamps tested were marked 50 volt with the exception of one lot which was marked 51. All were marked 16 C. P. except one lot which had no C. P. mark, and which were assumed as 16. All candle power observations were made by the writer. From four to twelve readings were made on each lamp according to the momentary condition of the observer's eyes and the momentary steadiness of the working current, and these readings averaged. Current and voltage were read by Mr. S. E. Hitt, who used a Weston direct current voltmeter reading to 150 volts, and a Weston ammeter reading to 1.5 ampere. These instruments were both checked against a Wirt standard voltmeter, using a shunt for the current reading, and a slight error in the former was allowed for.

No comments are made on the diagram, which speaks for itself. The following points should be uppermost in the minds of lamp-users, but some may not have yet learned them and others may not object to being reminded of them:

1st. The best lamp to buy is the one that gives the light needed for the least money—all expenses considered.

2d. The most satisfactory light to the user, other things being equal, is the one with the greatest uniformity; uniform from lamp to lamp, from moment to moment, from day to day. The difficulties in the way of securing this uniformity are great and occur in the rating of the lamp, in the regulation in the station, in distribution of the current, and in the tendency of lamps to "lie down" after use for a short time, dragging out a miserable existence of little use to any one except the manufacturer who wishes to make a life record of seventeen thousand hours, more or less.

3d. A good lamp badly rated will give worse results than a poorer lamp accurately rated. Lamps which are to burn together must have uniformity in candle power and efficiency. Variation among individual lamps in efficiency will have as bad an effect on lamp life as momentary variations in the E. M. F., and with the difference that it is a fault beyond the control of the operator.

4th. "Life" has no economical significance except when considered in connection with efficiency. Nominal efficiency, or efficiency when the lamp is fresh, has no such importance as the *average efficiency*, which in the usual sense of the term is equal to the total watt hours supplied during the useful life of the lamp divided by the total candle hours obtained during the same time.

"CANNOT AFFORD TO MISS ONE."

A SUPERINTENDENT of construction for one of the parent companies, who happens to be at work just now in Pennsylvania, writes us to give his address, and says: "I have not received last week's copy of your paper. It is so valuable to me I cannot afford to lose even one."

WHAT AN ELECTRICAL DICTIONARY MIGHT BE.

BY

Park Benjamin

THERE are certain propositions concerning an electrical dictionary which I take to be pretty nearly axiomatic:

1. The principal function of a dictionary is to define terms; that of a cyclopædia, to describe things. A cyclopædia may trench upon the province of a dictionary without losing its character. A dictionary cannot trench upon the province of a cyclopædia without containing surplusage and becoming itself a cyclopædia of an imperfect kind.

2. An electrical dictionary is intended for electricians and for those directly interested in ascertaining the exact meaning of terms. It is not intended for the lay reader; nor as an elementary text-book. The general public can find all the electrical terms that it needs set forth, with sufficient fulness, in existing text books and in the great dictionaries, such as the "Century."

3. The terminology of a science, unlike the words of a general language, is not the product of custom and slow growth. The terms are coined once for all, usually to represent, in brief form, a newly discovered fact or thing, and to avoid circumlocution or an unwieldly phrase for its expression. The maker of the term, as a rule, evolves it arbitrarily. In the great mass of cases, it is as often a mere word symbol as anything logically descriptive. It is the outcome of the sponsor's arbitrary judgment controlled by the existing state of the art.

4. Electrical words are the product of many minds acting at many different times. A person saturated with existing knowledge will create a word conformably to it; but just to the extent that his knowledge may be imperfect, so may his word become out of harmony, or even bear no relation to the existing terminology. From this it results that similar words may have different meanings at different times, and even at the same time.

5. From the foregoing it also results that the opinions of any one man as to the meaning of all the terms in a technical language are not proof of what the meanings are, but simply go to exhibit the condition of his own mind as influenced by certain external impressions. Another mind might receive a totally different set of impressions, and his own mind might equally receive a totally different set of impressions at another time. A dictionary, therefore, wherein one man attempts to define all the terms of technical language by the impressions formed in his own inner consciousness, must, of necessity be not a dictionary of what the terms *do* mean but of what he, as an individual, *understands* them to mean.

6. Progress in electrical science is a matter of days,—almost of hours. We are not only constantly discovering new things, but new views of old things. A dictionary which sets forth the views we take to-day, becomes inaccurate to-morrow, and perhaps wrong next year.

The science of electricity differs from other great branches of human knowledge in that we can clearly see the beginning of it. It does not get lost in the mazes of antiquity. It is practically all included between Gilbert's "De Magnete" and the last number of THE ELECTRICAL ENGINEER. The first electrical dictionary occupies one page of Gilbert's book, and contains about a dozen or so definitions. Among others, that of "electrics," "those things which attract for the same reason as the amber (electrum)." We have been adding to Gilbert's list for 292 years. If that great intellect could come back to earth again, our modern electrical dictionaries should show to him how the talent left by him in our keeping has multiplied; its whole multiplication, and not so much of it as we may happen to be using for our daily needs in the year 1892. If we want to describe the characteristics of a great river, the nature of its water, of its source, of its bed and of its banks, the speed of its flow and how it has been harnessed to human uses, we do not do so by specifying the height of the tide on a certain day and by the aid of an instrument filled with the errors of personal equation.

The dictionary made up of definitions arbitrarily evolved by the author is fast becoming obsolete. A glance at the new dictionaries of the great languages will show that modern philologists take into account all meanings of a word as understood by all competent minds, both past and present; and this, be it noted, in dealing with a general language which is necessarily of excessively slow growth, and where words stay unchanged for centuries. It is all a part of the tendency of modern science (a tendency so magnificently illustrated by Gilbert first and of late years most minutely by Darwin) to place before the student all of the data necessary to enable him to form an intelligent judgment for himself. The world nowadays accepts no theory, except provisionally; and it does not care a snap for any man's opinion unless it is backed up by the logic of incontrovertible fact. It is done with second-hand philosophy. It wants to see and hear the evidence; and the evidence itself, and not what somebody thinks the evidence is.

As I said before, all of this evidence in electrical science has accumulated within a space of three centuries. In making a dictionary we deal with recorded evidence. We can safely leave out terms which are so evanescent that no one has seen fit to write them down. This recorded evidence is available. It would not make a large library, as large libraries go, if the whole of it were massed together.

In fact, the reprinting of a library containing all known strictly electrical literature, would probably be considered a bagatelle by the Government Printing Office at Washington, and if made into volumes of similar size, would probably not aggegate one-quarter as many as have been sold of any one of the more popular, poor but pious novels of the late Mr. E. P. Roe. I have not counted the titles contained in that dreadful muddle, the catalogue of the Ronalds library, which includes not only the books which Sir Francis Ronalds had, but apparently every book that anybody else ever told him about; likewise newspaper clippings, and all sorts of fugitive literature, while its omissions are numerous and unaccountable. Judging from an experience of some ten years in building up my own collection, however, I should hazard as a fairly safe guess, that all the electrical terms coined between 1600 and 1870, together with all the uses of these terms, could be found in books and other publications aggregating not more than one-fifth of the total mass of electrical literature which has appeared. The immensely rapid progress since 1870, and the large increase in technical literature, notably newspapers, will doubtless require the investigation through later years to extend over a much larger percentage of the publications.

If the electrical dictionary of the future is made on the plan thus broadly outlined, it will define not only every term which has been used or proposed, but will define that term in the original language of the man who proposed it, and give his name, and state when he did it. Not only this, but it will give every meaning which that term has successively had, or enough meanings to show what material changes have occurred, and when, since it was first proposed. If it contained descriptive matter at all, that matter would merely be such as is best calculated to show how the term is or had been used. It would not be necessary in a book addressed to skilled electricians to give pictures of a voltaic cell, or a Wheatstone bridge, or a typical resistance coil, in order to explain what such things are. It would resolutely bar out definitions which do not define—such as attempts to state what electricity is by the time-honored though circular process of giving a new name to it.

Instead, for example, it would give all the definitions of electricity from Gilbert's explanation of the word "electric," the doctrine of effluvia, and Charlton's first use of the term "electricity" itself, down to perhaps Dr. Jacques' notion that the electric current "is a bodily forward movement of the ether." It would show, to give further examples, that such terms as "electromotive force," and "tension," and "charge," and "intensity," and countless others, had very different meanings from those of the present time, although they were abundantly used 70 years ago. That, for instance, even such a common word as "motor," or "electric motor," carrying with it as it does a practically undisputed meaning to-day, involved no idea of mechanical motion at the beginning of this century, and in fact, was Volta's name for his cell. It would show that many a capital definition has been made and forgotten. How many remember that Faraday defined "current" as "anything progressive?" It would show how the advancement of electrical science has been very like that of the zigzag lightning bending back sometimes on itself; that it is constantly taking up and adopting ideas long neglected; as witness the instances of Green, and of Ohm, and more lately, of Maxwell. It would show to the electrician all the meanings which the master minds of the science had given to a term, who its sponsors were, and at what stages of electrical history these significations were applied; unlocking, as it were, the mass of knowledge shut up in the word very much after the manner in which such writers as Trench and White have delighted in revealing the curious historical lore concealed in many oddly-formed words of our mother tongue.

In answer to the possible objection that such a dictionary would be of use only to people who take pleasure in grubbing into the past history of the science, I will give but one instance of its practical utility. A United States patent can be anticipated by what is shown and described in any prior patent or printed publication. There have been abundant cases (the storage-battery litigations, for instance) in which the courts and the experts have been called upon to explain the meaning of language contained in publications dating far back in this century. The language of these publications is too often interpreted by the meanings of to-day; and unless it can be shown to the courts by some convenient and available means that these meanings were just as non-existent at the time as was the invention which it is sought to overthrow by them, the courts are very apt to go astray. The principle of *lex temporis* applies to a scientific publication setting forth a generally accepted definition of the time just as much as it does to a statute once in force and now repealed; and it is just as absurd, for example, and in a sense just as unconstitutional, because *ex post facto*, to apply present significations to electrical terms used in the early part of the century, as it would be to apply the patent laws now existing to the solution of legal questions arising at that time and under the patent laws then in force.

The foregoing is not intended as a review of Professor Houston's practically new dictionary of electricity, but rather as an indication of what it is thought the dictionary of the future, constructed in accordance with modern scientific methods, might and perhaps ought to be. As an exponent of the type of dictionary-making which has hitherto generally prevailed, Professor Houston's work is probably as good as can be found. It serves the useful purpose of giving the latest definitions extant at the time of its publication; and probably it shows the general opinion of the electrical world as to the meaning of terms at its date. But, like all other works of its class, until sufficient time goes by to give it a new importance by reason of its scarcity and antiquarian interest, its practical value will be inversely proportional to its age. Subject to these objections, the utility of the book is unquestionable.

PLOTTING CHARACTERISTIC AND OTHER CURVES.

BY

Robert P. Dobbie

Having frequently had occasion to plot characteristic curves of machines, in some cases with small E. M. F. and comparatively large current, and in others with small current and very high voltage, I have found curves under these conditions to be so gradual that their true significance is not at once apparent to the eye. I have given the matter quite a little attention and have devised the following plan, which I use in my practice and find very satisfactory, and, I think, it will be of interest to some of the readers of the Engineer.

My method is to lay out the total amperes and total volts on an equal scale; for instance, supposing we have a machine of 1,000 amperes and 100 volts, and, supposing we used one foot to represent the 1,000 amperes in the horizontal direction, we would also use one foot to represent 100 volts. Of course in taking a characteristic curve, it is often necessary to go beyond the normal voltage at full load and the normal full load in amperes, but that does not affect the application of this principle; the normal full load of the dynamo is always a point on the diagonal of a square.

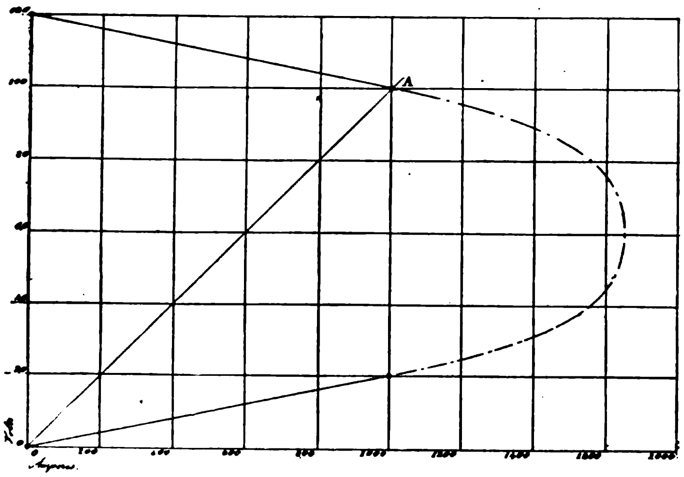


Fig. 1.

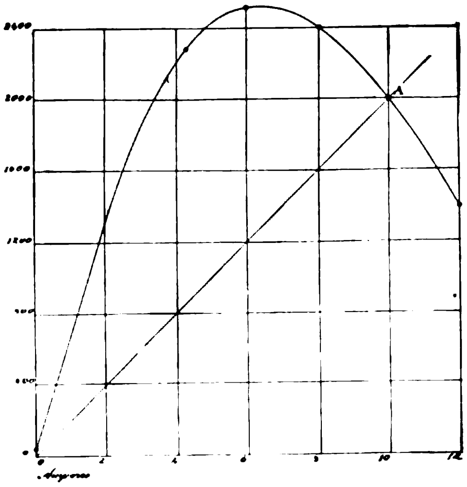

Fig. 2.

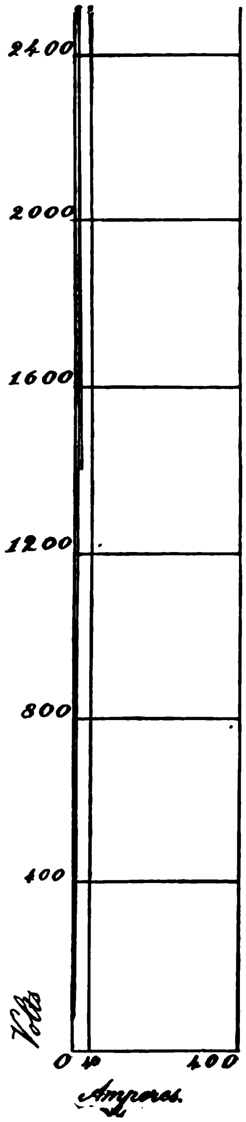

Fig. 4.

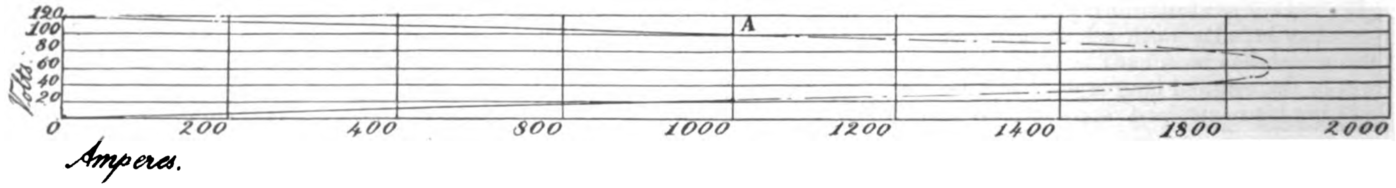

Fig. 3.

Referring to Fig. 1, we will suppose that 1,000 amperes and 100 volts is the normal full load output of a shunt-wound dynamo. This point, represented by a circle at A is equidistant from the zero line of amperes and volts; in other words it coincides with the diagonal of a square. In Fig. 2, which is a curve of a series-wound machine (not taken from actual practice), we have full load at 10 amperes and 2,000 volts. Here the point A is also on the diagonal of a square.

In Figs. 3 and 4 the same curves are plotted according to the usual rule and as laid down in Sylvanus P. Thompson's work, where scale of volts equals the scale in amperes; that is to say, if $\frac{1}{10}$ inch represented one volt, $\frac{1}{10}$ inch would also represent one ampere. It will be seen from comparison how very much easier it is to judge the curve laid out in the way I propose than by the usual method.

Another advantage is that two machines differing in size, but of the same general type, can be accurately compared; for instance, take two constant potential machines designed for 150 volts, one of them for 1,000 amperes and another for 500 amperes. If the physical properties of the machines were precisely the same, the curves would be identical; if the full load in each case were laid out to a scale of one foot, or any other convenient length, in the manner indicated, any variation due to quality of iron, etc., would be very apparent.

The principle here indicated can, of course, be applied to almost any of the curves now so largely used to exemplify problems in engineering; those curves that are continuous, such as a profile, speed and time curve, or line representing pull of a dynamometer, being exceptions.

EPICYLIC GEARING FOR ELECTRIC CARS AND ELEVATORS.

BY

Wm. S. Aldrich.

In a note recently printed[1] entitled "An Hydraulic Gear for Street Cars," it is stated that "A patent is about to be issued for an interesting hydraulic gear or clutching mechanism, the invention of Mr. Finis M. Barney, of Kearney, Neb. It is an application of the differential or epicyclic principle, with an hydraulic instead of a fixed connnection." At the end of the above article a modification is referred to, in which the armature and field both are said to revolve. Several features, of special interest to the electrical engineer, are here brought together; and the writer presents, in connection therewith, an outline of the work which he has done in this field during the past year.

The problem presented has been to devise some intermediate variable-speed transmission machinery, between the armature shaft and car axle, by which the electric motor, working at its best efficiency, may be driven at a uniform speed in one direction—while the intermediate gearing allows of the car remaining stationary, or being driven forward or backward at any desired speed within the limits of the combination.

The principle of what is known in mechanism as the *epicyclic train* has seemed to offer many ready solutions. As a train of gear-wheels, having a fixed or constant velocity-ratio, it requires two electric motors, capable of being *slightly* varied in speed with respect to each other, in order to produce a rotation of the arm of the train, keyed to the car axle. This is the form of the Edison epicyclic gearing[2] for street cars. In another form, with a train of gear-wheels, arranged on the epicyclic principle, one electric motor may suffice; but a clutch is necessary to bring about the slight variation in speed that is required to operate the epicyclic train. The Baldwin[3] epicyclic gear and friction clutch are developments of this form. The McQuesten gear employs a similar principle but with an electromagnetic clutch.

The epicyclic principle will be understood by referring to Fig. 1. This represents an ordinary epicyclic train of spur gear-wheels driven by electric motors. The motor armature M_1 and gear-wheel A are secured to a sleeve, loosely turning on shaft P P, such as a car axle; M_2 and D are also loosely sleeved on the same shaft. The gear-wheels B and C are keyed to the same shaft S S. The arm X, as a crank arm, is keyed to the shaft P P, but loosely mounted on shaft S S.

Three principal combinations of these three elements are possible. (1) Arm X, fixed; the motor M_1 will drive M_2 as a dynamo, or *vice versa;* the fields being held stationary. (2) Shaft P P held in fixed bearings, fields stationary, both motors M_1 and M_2 set in operation; the arm X will then turn around and carry the shaft S S and its wheels B and C around the shaft P P, when the motors revolve at different proportionate speeds. The arm X turns in a direction dependent upon the direction of rotation of the motors M_1 and M_2, and at a speed proportional to the speed of the motors and the number of teeth on the gear-wheels. When the four wheels, A, B, C and D, have the same number of teeth, and (*a*) the motors rotate at the same speed in the same direction, there will be no rotation of the arm X; (*b*) the motors rotate at different speeds in the same direction, the arm X rotates at a speed equal to half the difference of the motors' speeds. (3) Shaft S S held in fixed bearings, fields stationary, simply inverts the combination, and causes the secondary shaft S S to become now a primary shaft, while the former primary shaft P P becomes now the secondary shaft. Several minor combinations will suggest themselves; but the above serve to show the differential nature of the ordinary gear-wheel epicyclic train, when a *slight difference* of speed is produced at the driving wheels A and D.

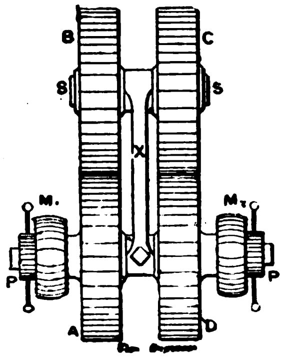

FIG. 1.—CONSTANT SPEED EPICYCLIC TRAIN.

The primary shaft P P may be driven forward or backward at different speeds, if the two motors are slightly varied in speed, and this requirement is the inherent defect of this form, where gear-wheels with constant velocity ratios are used. Of course, one motor at a constant speed may be used with a clutching device, but the combination is non-reversible. All speed variations are of necessity external to the epicyclic train itself.

The variable epicyclic train[4] was brought out by the writer, May 21, 1891, to obviate the objectional features of the constant-speed train, as above described. The principle is shown in Fig. 2. As long as the belt is normally central, there is no *tendency* for the arm X to rotate, as there is no lost speed to be made up. When the belt is shifted, there is an obvious tendency for the arm X to rotate in one direction or the other, according to which side the belt is shifted, and this results in the rotation of the shaft P P, to which the arm X is keyed, the constructive features remaining the same as in Fig. 1. In this combination, it is possible to obtain with a given shaft P P, a variable velocity, in either direction, from a shaft or motor moving at a constant velocity in one direction. Moreover, this change may easily be made continuous, without in any way interfering with the crank-arm X, from a maximum in one direction to a maximum in the other. Speed cones, pulleys, or other simple variable-speed gear may be introduced into one or both of the arms. All speed variations are internal in the arms of the epicyclic train itself.

[2] THE ELECTRICAL ENGINEER, Sept. 17, 1 90, p. 303.

[3] THE ELECTRICAL ENGINEER, Oct. 22, 1890, p. 436.

[4] Submitted to the Committee on Science and Arts, Franklin Institute, Philadelphia; report made by the sub-committee Sept. 18, 1891, and adopted by the committee, Nov. 4, 1891.

Having arrived at the *variable epicyclic gear* by using well-known mechanical elements, as parts of the train of mechanism, it remained to develop the applications of the same principle by other modes of connection, such as by electromagnetic, hydraulic, and pneumatic means. The elastic nature of the medium employed in pneumatic connection is too unreliable for any definite variable-speed gear; but the characteristic features of the electromagnetic and hydraulic connection in mechanism render these of useful application.

The electromagnetic epicyclic[5] gear was brought out by the writer, Aug. 23, 1891. Gear wheels are replaced by constant speed dynamotors, cone pulleys, or speed cones, by variable-speed dynamotors; and these electromagnetic elements being substituted, as it were, in the epicyclic train, produce a constant or a variable speed epicyclic combination, useful for electric street cars, elevators, hoists, etc.

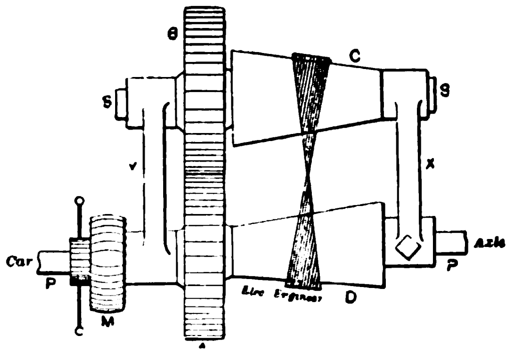

FIG. 2.—VARIABLE EPICYCLIC TRAIN.

The hydraulic epicyclic gear was developed by the writer, Sept. 1, 1891. It consists in the simple substitution of an hydraulic connection in the arms of an epicyclic train for the mechanical modes of connection heretofore employed. These hydraulic elements being thus substituted result in a constant or variable speed epicylic combination. Rotary pumps, turbines, or other hydraulic motors replace the dynamotors of the electromagnetic epicyclic, and the gear wheels and speed cones of the ordinary variable speed epicyclic gear. This hydraulic connection between the primary and secondary shafts, may be used for all purposes and with the usual advantages of the epicyclic combination.

As with the mechanical and electromagnetic devices already mentioned, the hydraulic epicyclic will produce variable rotation of a given shaft, in either direction, from one motor sleeved thereon, and driven at a constant speed in one direction. The hydraulic pump and motor, connected by an hydraulic circuit, in one or both arms of the epicyclic train, form a kinematical equivalent to the dynamotor combination. The hydraulic circuit, in this mode of connection, may be worked as a closed circuit, or open, and in connection with an air cushion or air chamber. The hydraulically connected motors in one or both arms of the epicyclic train, form "chamber gears" (Reuleaux), and perform all the functions of ordinary chamber-gear combinations,—whether as constant or variable-speed mechanical devices, or as ordinary rotary pump or turbine chamber-gear combinations, working with oil or water. The chamber gears here introduced in the arms of an epicyclic train, may be similar or dissimilar in construction, and equal or unequal chamber gears,—forming here "pressure-organs" (Reuleaux) which are kinematically equivalent to the simple constant or variable speed mechanical connections similarly used in the former cases.

As in the other two modes, the hydraulic connection may be internally or externally varied, in such a way as to change the speed relation of one or both of the train arms; or, to bring about a definite tendency to a change of speed between the primary and secondary shafts. This tendency to produce such a change of speed, is the peculiar feature of the *variable* epicyclic gear, and on which principle its chief merits rest. It is only an apparent tendency, for it is at once compensated for by producing a definite rotation of the arm X. Therefore, all of these varied modes of connection are but kinematical equivalents,—resulting in the same characteristic tendencies and capable of the same applications as variable speed epicyclic gears. The fundamental principle is equally developed in each of them, by a variable speed mode of connection, within the arm of the epicyclic train itself.

The question of rotating both the field and the armature arises at once in using the dynamotor as an electromagnetic connection in an epicyclic gear. In fact, it is upon this very principle that the successful operation of this form of the variable epicyclic gear depends. The matter has been considered at length, in this connection, when developing the electromagnetic "kinematic chain"[6] (Reuleaux). From the point of view of the kinematics of electromagnetic machinery, the armature and its field are elements forming an electromagnetic turning pair. As such an elementary combination, therefore, either may be rotated while the other is held stationary; or, both may be rotated at such proportionate speeds as shall cause the lines of force to be cut at the same rate as when one of them is held stationary. The same principle is applied in the Brackett cradle dynamometer, in which the field is freely pivoted, and the torque measured by a weighted lever or a spring balance. In this case, too, the mutual action of the field and armature is analogous to that considered, for the combinations of electromagnetic epicyclic mechanisms; for, if the field does not actually revolve at a given speed, there is a decided *tendency* for it to do so; and, this is all that is needed, whether in measuring the torque by a reacting spring-balance, or in causing rotation of the epicyclic train arm in the performance of useful work on the primary shaft. Lieut. Patten some time ago developed a form of double-rotation motor,[7] *i. e.*, one with revolving field and armature.

The efficiency of transmission in each of the three typical modes of connection in the variable epicyclic gear, will depend largely upon its design, construction and management. Mechanical devices have such a low efficiency as to more than offset, in almost all ordinary cases, the hoped-for gain in the motor efficiency. Electromagnetic and hydraulic connections should have almost the same efficiency, for the same number of transformations. In these, however, the efficiency of the epicyclic combination will be quite variable of itself, being affected by the same causes which now lower the efficiency of street car motors. The attention, however, which has been given to this question of intermediate gearing in many quarters, has evidently proceeded from a belief that some efficient form of gearing and efficient mode of connection could be devised and designed, which would strike a balance of a decided gain in the combined efficiency of the gearing and motor.

Perfection in every machine is a matter of development.—Coleman Sellers.

THE COMMERCIAL RATING OF INCANDESCENT LAMPS.

ELECTRIC lighting has given rise to not a few anomalies, but none, we think, are more difficult to explain than the differences which exist in the severity with which the purveyors and consumers of light look upon variations from standard candle-power as between arc and incandescent lamps. While the 2,000 c. p. arc lamp *nominal*, for the most part sends forth its rays nightly at a brilliancy probably not much exceeding 1,200 c. p. without calling forth more than an occasional grumble, the slightest falling off in candle-power in the incandescent lamp is sure to raise a howl of indignation from the consumer; and to his complaint is added that of the operating company, when the life of the lamp is unduly curtailed. Tests have often been made in order to ascertain the candle-power and life of incandescent lamps, and they go to show that in general an improvement in the efficiency of lamps as well as in life has been effected. Nevertheless, there are marked variations still to be found in the lamps of different manufacture, the reasons for which can be readily understood. The commercial rating of incandescent lamps, as is shown by Mr. Charles Wirt in this issue, is a very uncertain factor in determining the all-around qualities of a lamp, and he sums up very well by saying that the best lamp to buy is the one that gives the light needed for the least money—all expenses considered. Life and efficiency combined must determine the true value of a lamp, and Mr. Wirt's caution that the rating to be found on lamps should be carefuly checked by consumers is a very timely one. It might be argued by some that the small number of lamps of each kind tested by Mr. Wirt would scarcely allow of obtaining average results, but as far as they go they indicate the precautions which ought to be taken in order to obtain the best results in the employment of incandescent lamps.

RAILWAY ELECTRICITY.

THE meeting of the railway superintendents, held in Denver, Col., last week served to bring out strongly the intimate connection, in many ways, between the modern railway and the electric current. Beyond the now indispensable adjunct of the telegraph, the electric signal and many minor applications, railway managers are brought face to face with that larger and more important subject of electric traction, and it is well that Mr. Charles Selden drew the attention of his colleagues to matters which they may be called upon, at any time, to seriously consider in their daily work. The figures he gave as to the relative proportion of net profits to operating expenses of steam and electric roads were very significant as showing the greater remunerativeness of electric railways. To be sure, the traffic of both is somewhat different in its nature, but even to-day suburban roads, which are now barely paying expenses, as Mr. Selden pointed out, could be made profitable, and we are glad to learn that if the experiments about to be undertaken by the Baltimore & Ohio Road, at Baltimore, in the application of heavy locomotives to the hauling of their trains through the tunnel proves successful, it will be followed by the converting of the suburban steam road of the Baltimore & Lehigh Railroad into electric. The prospects and limitations of electric railroading on the standard-gauge roads as discussed from a mechanical and electrical standpoint in Mr. Frank J. Sprague's inaugural address, before the American Institute of Electrical Engineers, in Chicago, must be viewed with satisfaction by all electrical engineers interested in the progress of electric railroads, inasmuch as the conservative tone adopted by Mr. Sprague will serve to instill confidence in the minds of many who are prone to look upon the somewhat visionary schemes of some electrical promoters as the prevailing ideas of the general body of electric railway engineers.

DRAWING CHARACTERISTIC CURVES.

GRAPHICAL methods which present to the eye symbolized pictures of any given law of action are so convenient for study and comparison that their employment naturally suggests itself in all cases where they are applicable. In the case of the dynamo, especially, the study of the characteristic curve has done not a little towards its improvement, but, as Mr. R. S. Dobbie shows on another page, much of the value of such curves depends upon the selection of the proper scales for abscissæ and ordinates, respectively. An injudicious selection may frequently so distort the curve as to completely hide its true signification, while on the other hand a proper standard, not only brings out the true nature of the actions which the curve is intended to portray, but also allows of a direct comparison between different curves.

THEORETICAL ELEMENTS OF DYNAMO-ELECTRIC MACHINERY.—VII.[1]

BY

A. E. Kennelly

THE INFLUENCE OF IRON IN AND ON THE MAGNETIC CIRCUIT.

We have thus far confined our attention to magnetic circuits devoid of iron, circuits surrounding electric currents, and far removed from any of the magnetic metals. We have seen that in all such circuits, there will be a distribution of potential wherever there is a flux, except within the substance of the active conductors; that this potential and flux can always be determined by rule, however difficult the numerical calculation may happen to be, so that the elements of the circuits, such as we have defined them, namely M. M. F. (including potentials), flux, flux density, reluctance, and permeance, are all essentially determinate quantities, depending only on the strengths of the currents, and their geometrical arrangement. We now proceed to consider the effects of introducing iron into magnetic circuits. It will be seen that the changes thus effected are not fundamental but superstructural. The iron alters in no way the original system, but superposes upon it a new system, which the original one has induced, and these two, merged together, form a composite system whose resultant effects are presented to view.

The first evident effect following the introduction of iron into a circuit is an increase in the flux. In order to examine this under the simplest conditions, we will select that geometrical system which we know establishes a uniform intensity, and in a direction of uniform curvature—a closed circular solenoid—with a mean radius r and a small cross-sectional area a. Suppose this to be constructed of wood, and wound with Nc current turns. Then by the results of Chapters IV and VI we may consider that we have everywhere within the wood an intensity of $\frac{2\,Nc}{r}$, which we may call the prime intensity. Now suppose the wooden ring exchanged for one of iron having the same dimensions. We should find experimentally that the flux, and consequently the intensity, had everywhere increased in some ratio, μ, whose magnitude would depend on the quality of the iron, the value of the prime intensity, and the manner in which that prime intensity had been brought to bear upon the iron. But leaving these influences for later consideration, we should find that the flux had increased from F to $\mu\,F$. There would be no other magnetic change. Physically, of course, the magnetic structure and molecular condition of the iron must be different from those in wood, but so far as the magnetic circuit and its various elements are concerned, precisely the same effects would be produced within the wood, if the excitation on it had been increased from Nc to $\mu\,Nc$ current-turns. ($10\,Nc$ to $10\,\mu\,Nc$ ampere-turns.) There are only two ways in which the flux in this circuit can have been augmented by the substitution of iron. Either by an increase in the permeance, the M. M. F. remaining constant, or by an increase in M. M. F. with the prime permeance unchanged.

Here as well as in the corresponding case for the galvanic circuit, purely numerical considerations afford no choice between the two alternative hypotheses. The electrical resistance of a wire might just as well be considered as due to the effect of a counter E. M. F. produced in a definite relation to the current strength. All that we can observe is a fall of pressure along the wire, and this might be ascribed either to opposing E. M. F. e, or to its numerical equivalent $c\,r$. There are cases, such as that existing in the arc lamp, where the drop in pressure, largely due to counter E. M. F., was long ascribed entirely to resistance, and a distinction can only be effected in these instances by observing that the drop in pressure is not uniform in distance, or that residual E. M. F. survives the working current. For conductors in general, however, the principle of resistance is much simpler than that of its numerically equivalent counter E. M. F., and its practical advantage is decisive.

With the magnetic circuit of iron it is otherwise, for, assuming the change in flux to be due entirely to diminished reluctance, the reluctance of iron is not constant as is the resistance of metals in the galvanic circuit at uniform temperature, but varies with the conditions of the circuit; while on the other hand, it is found that after the current has been interrupted in the solenoid, a residual flux exists in the iron. If we are to retain the definition that M. M. F. and flux stand in the relation of cause and effect, it follows that there is residual M. M. F. in the iron. It is therefore more probable that the increase in flux is due to M. M. F. induced in the iron and coinciding with the prime M. M. F. in direction. Since the maintenance of flux does not imply expenditure of power, this does not violate any law connected with the conservation of energy.

According to these principles, the uniform prime intensity of flux in the solenoid, excites in the iron, when introduced, a uniform M. M. F. which will exist in every centimetre of iron under stress along the circuital path. Since the prime M. M. F. has increased μ times, the induced M. M. F. in the iron must be $\mu\,M - M = M\,(\mu - 1)$. Similarly the difference of potential primarily existing between any two planes drawn across the ring will have increased μ times as though the original P. D. of $\frac{2\,Nc}{r}$ per cm. had been increased by an induced P. D. of $\frac{2\,Nc}{r}\,(\mu - 1)$.

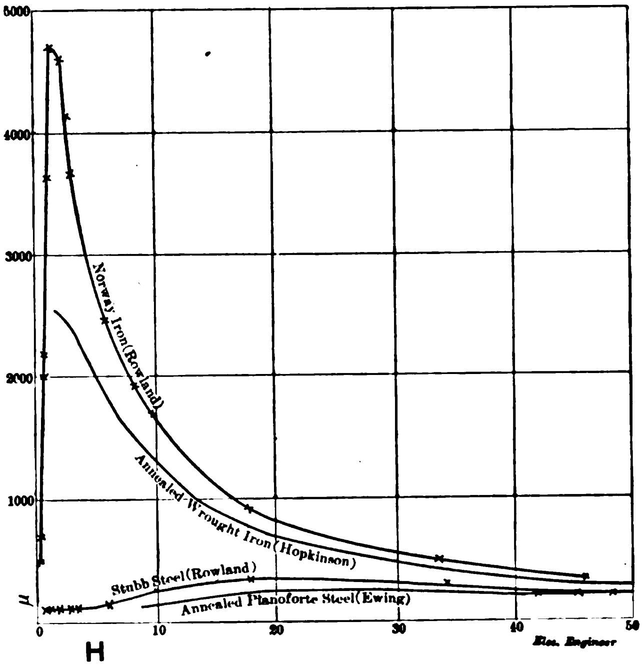

FIG. 15.

There are thus two complete and associated systems of P. D. flux, and intensity, in the iron ring. The first is the prime system that would exist if the ring were of non-magnetic material. The second is the induced system $\mu - 1$ times greater. On interrupting the current in the solenoid, and thus withdrawing the prime system, this induced M. M. F., flux and intensity remain. Strictly speaking the induced system does not remain complete, but suffers to a greater or less extent when the excitation is withdrawn, but under favorable conditions, as much as 95 per cent. may be conserved.

---

[1] *Copyrighted 1892, by A. E. Kennelly.*

The numerical value of μ, the factor of augmentation due to the presence of iron depends upon the chemical and physical structure of the latter. For a given prime intensity, it is greater as the iron is softer and more nearly pure, while it is materially reduced by small degrees of impurity, especially when these consist of carbon or manganese. A value as high as 4,600[1] has been recorded for Norway iron in a particular case, and on the other hand a result as low as 1.85 has been reached under very exceptional conditions.[2] Fig. 15 gives some curves of values for μ with several qualities of iron. The abscissæ represent prime intensities, or the flux per square centimetre that would exist if the iron were removed and replaced by non-magnetic material. We know that this is the gradient of potential, and that in the circular solenoid it corresponds to the uniform fall of potential per centimetre of circuit. Prime intensity is commonly denoted by the symbol H. For example, in Norway iron, μ is seen to be 1,000 for about 16 C. G. S. lines per sq. cm. $(H = 16)$. If this particular intensity were produced in the interior of a closed circular solenoid, the complete introduction of Norway iron of this quality into the core would raise the intensity to 16,000 lines per sq. cm. and the P. D. per centimetre of circuit would be raised from 16 to 16,000 ergs per unit-pole. If the circumference of the ring were 200 cms., the exciting M. M. F. would have been 3,200, and the total M. M. F. after introducing the iron 3,200,000.

COMING DEVELOPMENT OF ELECTRIC RAILWAYS.—II.

BY FRANK J. SPRAGUE.

No one will question the capacity of a motor to do the necessary work required, or to make a speed superior to that of the steam locomotive provided sufficient energy be delivered to its terminals, but we must deal with existing or probable methods of supply. It is true that the speed at which a train is propelled by steam has only increased about 50 per cent. in 60 years, for in 1832 the "Matthew Baldwin" often made a speed of a mile in a minute; but we must not confound speed with power, for while the maximum speed has not been so materially increased, the endurance, the perfection of the mechanism, and the economy of performance have made great strides, and the increased speed, which is by no means the maximum possible of a locomotive *per se*, has been attained at much higher powers, and the schedule time has been shortened principally by cutting down grades, straightening curves, filling up ravines, abolishing trestle works, replacing wooden bridges by permanent ones of iron or stone; by the use of heavier and stiffer rails, better switches, improved methods of automatic signaling, the interlocking switch and signal system, and the abolition of grade crossings; in short, by improvements in details and management which permit of higher speeds on more extended sections of road because of greater safety, lower traction coefficients, and a greater degree of confidence possessed by the locomotive engineer.

All these things are necessary for high-speed electric railways, and any general improvements that will be of benefit to the latter must necessarily be of service to the former. Any predictions which are made concerning the future of electric propulsion, either in ignorance or disregard of the possibilities of steam duty, and the limitations necessarily existing in all systems of transportation, deserve, and will receive, little consideration. Hence, let us note a few recent locomotive performances.

Almost every one is familiar with the remarkable run recently made by a Schenectady locomotive hauling a special train on the New York Central Railroad, when the distance of 439½ miles from New York to Buffalo was made at an average speed of nearly 60 miles per hour, and which was the precursor of the Empire State Express, which makes the regular run at an average speed of over 52 miles. More recently, we have accounts of an interesting record, made by a well-known writer, on two runs between New York and Albany, on which a large number of indicator cards were taken. The weight of train was about 270 tons; the steam pressure varied from 160 to 170 pounds. From an inspection of about a dozen cards, the indicated horse power varied from 551 h. p. at 44 miles to 1,120 h. p. at 78.9 miles. At 60 miles per hour the train resistance is stated to have been 15 pounds per ton, and at 70 miles, 17.10 pounds per ton. About seven pounds of water were evaporated per pound of coal. A remarkable statement concerning this performance was made by Mr.
out by
those who
comparative
recent number
the
whole trip shows
average
expenditure of only
per h. p. per
hour. This is far better than many stationary engines. On the New Jersey Central Road one schedule time is 86¼ miles in 89 minutes, which is made where there are a number of necessary slackings. On the 13th of May the time was taken of the speed of a Baldwin compound locomotive for a considerable period of time on one of the regular runs. Ten continuous miles were made in 452½ seconds and five were made in 222 seconds. The fastest time taken was 44 seconds, and the slowest noted was 47.

On the 26th of last February a similar compound passenger locomotive running on the same road broke all steam records by running a mile in 39¼ seconds, or at the rate of nearly 92 miles per hour. At this speed the indicator cards showed 930 h. p., and the drivers, which are 78 inches in diameter, were making 395 revolutions per minute.

In the very near future, I expect to have the pleasure of riding on a locomotive when going at these high speeds, and I presume my respect for steam locomotion will not be diminished thereby, nor, on the other hand, will my confidence in the possibilities of electric propulsion, under the proper conditions.

Experimental runs have been made with an electric locomotive at the rate of a mile in 30 seconds, that is, 120 miles an hour, and I confidently expect some day to go at that rate. But it will be under special conditions and not on the regular trunk lines of this country, and it is the height of folly to suggest that these steam trunk lines are to be abolished.

In making these very high-speed runs there is not much attempt at maximum economy of coal consumption, the necessity being to generate steam as fast as required by the cylinders; but on taking an average of five trips, I find that there was evaporated 7.19 pounds of water per pound of coal used and 9.41 pounds of water evaporated per pound of coal consumed. The total weight of train varied from 218 to 241 tons. The personal equations of engineer and fireman necessarily enter seriously into steam operations, and this, compounded of course with the peculiarities of each engine and the conditions of service, is shown in railroad reports.

In this connection, I recently inspected a number of engine sheets. On one, which gave the duty of 25 engines, the average total cost per engine mile was 10.85 cents, of which 2.66 was for fuel. The total cost varied from 6.8 to 19.24 cents, and the fuel (wood) from 1.96 to 4.77 cents. On another sheet giving the performance of 22 engines, the total cost per engine mile was 14.70 cents, of which the fuel cost 4.61. The total cost varied from 8.82 to 27.98 cents, and the fuel cost from 2.04 to 7.48.

In still another, that of the performance of 18 engines, the total cost per engine mile was 14.73 cents, of which the fuel (coal) cost 6.62 cents. The total cost varied from 10.04 to 22.52 cents and the fuel cost from 3.83 to 13.84 cents.

In discussing the electric system there is often a confusion of statements with reference to economy. Despite the undoubted fact that the electric motor can probably be run at variable high speeds with less variation of economy than can the steam locomotive, we must not forget that in the latter we are considering the economy of the unit as a whole, not merely of the steam cylinders, but also of the boiler and the furnace. In electric propulsion a similar comparison of economies must take into account the variable duty of the central station and the losses on the line as well as those in the motor, and where single units are used the variation in economy of the whole system would be much greater than in the steam locomotive. There will be only a reasonable fixed efficiency of the central station and the line when the number of units is large enough to make the load on the central stations nearly constant.

Let us now consider another class of duty. Some time ago I made a very careful analysis of the work done on the elevated roads in New York City with a view of determining the coal consumption and the duty performed by the locomotives. At the time this investigation was made, now nearly seven years ago, there were in use on the Third avenue division, 68 trains at one time, running at very close intervals. The weight of the trains was from 80 to 90 tons; the speed was often as high as 20 to 25 miles an hour; stops were made every third of a mile; in short, the duty demanded of the engines was exceedingly severe.

The maximum indicated horse power of the locomotives was found to average about 163 h. p., although on occasions these locomotives have been worked up to 185 h. p. Work was divided approximately as follows: Acceleration in starting 59 per cent., lifting 24.3 per cent., and traction, 16.7 per cent. The average horse power exerted was 70.3 h. p., considerably less than one-half of the maximum.

The work on the line was so distributed that there was an almost constant total duty of about 4,500 h. p. The locomotives were on duty 20 hours, but used steam only six hours, and, including all losses when standing still, together with the amount

or
s are
ce when

that with an
efficiency he energy of the
train being re ve coal expenditures
between steam and ele be about in a ratio of two to one, but if the energy of the train was returned to the line to the extent which I believe it is possible, then the relative expenditures of fuel would be in the proportion of seven to two. Since the coal charge on the four divisions was at that time about $550,000, it can easily be seen, that independent of any question of saving in the care of the structure and any reduction or depreciation of the motor equipment, the fuel saving wonld be sufficient to pay a good interest on the cost of an electric equipment, and a large interest on the cost of electric equipment, minus the value of the present engines. I have no reason to doubt the soundness of the conclusions I then made.

You will have here in Chicago, however, a somewhat more advanced condition of affairs. A compound type of locomotive has been adopted for the elevated road service, and I believe it will show an increased economy over that of the operation of the New York roads. Consequently, in discussing the question of economy, it is necessary to get full information concerning the duty which will be done here.

In discussing high speed possibilities and limitations, the testimony of Dr. Dudley as given in a discussion of a paper before this Institute on the 24th of February, 1891, is interesting. There are, generally speaking, three distinct elements constituting the resistance to train movement on a level, and they have a most important bearing when we consider the operation of long or short trains and at high speeds. One of these elements is the friction of the train in its bearings; with good rolling stock this is about eight pounds per ton. For all reasonable speeds it is probably fairly constant, provided the lubrication is good. Another element is that of air resistance which varies with the shape of the forward end of the train, the condition of the air, the direction of the wind, and the velocity of movement. The third I may call the train lifting or rail bending effort, which depends upon the weight and stiffness of the rails and solidity of the road bed.

Dr. Dudley stated that on the New York Central system he found that trains of about 250 tons when running at a speed of a mile a minute, have a resistance of from 10 to 12 lbs. per ton, but that on short trains of two or three cars the resistance sometimes ran as high as 35 or 40 lbs. per ton. This is probably due not to any change in the friction of the bearings, but to the fact that the air resistance enters as a much higher component of the total.

It at once emphasizes the fact that the operation of short trains at high speeds must, no matter how good the track or how favorable all other circumstances, be with a train resistance higher than that required by long and well-vestibuled trains. Such a shape can be given to the front of an electric locomotive as will make the air resistance not over one-half that presented by a plain surface of equal cross-section and perpendicular to the line of motion, but even this fact does not alter the other, that the resistance per ton must be higher for small trains than for large ones.

Mr. Dudley further stated, in speaking of the influence of stiff rails, that the difference in power required on the Chicago Limited when running on an 80 and a 65 pound rail was from 75 to 100 h. p., that is, somewhere between 10 to 12 per cent. of the power actually developed, and he estimates that with a 105 lb. rail which is nearly twice as stiff as the 80 lb. rail there would probably be saved another hundred horse power, making a total saving of a quarter by less than doubling the weight of the rail. In his opinion it is perfectly safe to run a steam engine 120 miles an hour on this heavy rail.

Such rail improvements increase speed possibilities with present engines, but we have not reached the limit of steam duty. Almost all the locomotive work of the United States has been done up to the present with simple engines. Their weight and capacity have been increased, their steam pressure raised until the standard is now about 140 lbs. Within recent years, however, the compound locomotive has come into use, and there is a comparatively large number of them in daily service. The steam pressure has gone up to 180 lbs. as a standard, working sometimes as high as 200 lbs.; but these are by no means the limits of steam pressure. On the Paris, Lyons and Mediterranean Railway, the standard for steam pressure for compound locomotives is 250 lbs. The compound locomotive has still its battle to fight, but I think he would be a rash man who will say that the days of still higher steam pressure are not to come, and that the triple-expansion locomotive will never exist.

Speed, capacity and coal economy are, however, not the only questions to be considered in railroad operation, and in discussing the general subject it will be found that the signaling and braking questions at high speeds are serious ones. Undoubtedly an electric train with distributed motors, making the weight of the train available for traction, could, by using the motors as dyanmos, return the energy of the train to the line from the highest to mean speeds and then on a local circuit be more quickly and effectually slowed down and stopped than where shoe brakes are used, and both methods of course would be available. But if using a motor ahead of a train then there will be comparatively little difference in the stopping power.

When riding at 60 or 70 miles an hour, it is a very quick stop to bring a train at rest in less than 2,000 feet. This is often as far as any signal can be made out, especially when the weather is at all thick. Hence we may expect to find on electric railroads, if high speeds are to be attained, and quite possibly also on steam railroads, an extension of automatic signaling so that trains indicate on more than two sets of signals. At present the practice is to divide the line into sections, and when a train passes a certain point it sets a danger and a cautionary signal, dropping the danger signal on the section just preceding, and the cautionary signal on the one beyond.

Turning now to the greater powers, we must not confuse the terms "large powered" and "trunk line" work. There are two statements which I think will need no corroboration. If we had a continuous train movement completely occupying a track system, there can be no question but that its operation from a central source by electricity would be more economical than if operated by steam locomotives. So too, if a large number of units in reasonable proximity are moved, and the stopping and starting so regulated that the total demand upon the central stations is fairly continuous and equal, then there is no question as to the economy of electric propulsion as compared with steam.

On the other hand, the operation of a single or very few units over a long distance would be so uneconomical and afford so small a return on the invesment required as to make it prohibitory. Between these two lies the condition of operation where steam and electricity meet on planes of equality; as the number of trains decreases, steam operation is the more economical; as the number increases electricity must be preferred.

In discussing the use of electricity instead of steam, a well-known steam engineer recently stated that in his judgment it must be conceded that electromotive force for the propulsion of cars will not be economical except for suburban traffic and upon certain sections of important trunk lines like the New York Central between New York and Albany, the Pennsylania system between New York and Philadelphia, the other lines of like character where it is necessary to dispatch a large number of comparatively light trains every day, and at short intervals. The principal field for a power of this kind would be in suburban service long enough to make the ordinary street electric cars unpopular because of the time required, and in such cases as those mentioned above; also for moving freight trains in cities, that is, for the performance of transfer service. This is precisely in line with the arguments I have advanced from time to time, and which I illustrated in a paper before the National Electric Light Association at its Convention in Kansas City, where I outlined the possible service between New York and Philadelphia, which I believed to be practicable, and to which I will again refer.

I must repeat that it narrows itself down to the one question as to the number of trains operated between two terminal points. Make that number of trains sufficiently large, and the electric motor is the best means of propulsion, whether for high or low speed, whether for large or for small cars. Decrease this number and we must rely on steam propulsion; or to put it in another way, the answer to the query, Will electricity take the place of steam for railroad purpose? is: Only in part, and then only when the number of units operated between the terminal points is so large that the fuel economy would pay a reasonable interest and depreciation of the necessary cost of the central station and the system of conductors.

Of course I do not in this general reply consider those special cases where advantages are to be gained for which there is a return for capital in another direction. Such a case is that of the Baltimore Tunnel, where the investment and cost of operation will be greater than that for steam propulsion; in fact, there will practically be no economy in power because the steam locomotives are not done away with but simply unused for a period of a little over a mile. There is in this specific case, however, the incidental advantage of doing away with the necessity of a ventilating plant and yet getting rid of the annoyances incidental to tunnel service. Trunk line transportation being a great problem, we should not attempt the simultaneous solutions of all the questions involved, but instead, determine what those questions are, consider their sequence, and the probability of success and solve them in their order.

A CORRECTION.

In the article entitled "The Economy of Condensing Engines Overrated," by Mr. J. H. Babcock in our issue of June 1, a misprint made the last paragraph but one read incorrectly. It should have read as follows:

"The case is simply this: Given a certain amount of fuel to be burned under a battery of boilers which produces in steam a certain number of heat units. The best we can do in engine work leaves more than 80 per cent. of these units still in the steam after it has passed the engines, and which escapes in the water from the condenser if one be in use."

Legal Notes.

THE EDISON INCANDESCENT LAMP PATENT—FINAL HEARING BEFORE THE U. S. CIRCUIT COURT OF APPEALS—III.

REFERRING next to an affidavit made by Mr. Edison in a certain proceeding in Canada in reference to this invention, General Duncan contended that Mr. Edison had regarded "purely structural carbon" as the only kind available for his use. This was the high resistance carbon of the patent; it was one of the things he had had in mind when he used that undefined term "filament"; it was the thing which he had said in his affidavit was the chief element of his success. But the defendant's lamps had been made by a process of hydrocarbon treatment; they had been shaped either from paper or from tamidine and then carbonized, and afterwards subjected to a hydrocarbon treatment by which mineral carbon had been deposited in their pores and their resistance reduced from 50 to 90 per cent. Was that the kind of carbon which Mr. Edison had said was absolutely essential to the making of an incandescent lamp? He had discovered, as he says, that only a purely structural carbon could be used, unmodified by any treatment tending to fill its pores with unstructural carbon to increase its density or to alter its resistance. Was there any special reason in the prior art for Mr. Edison to impose such a limitation upon this new thing? In 1887 Fontaine had tried certain experiments with the Konn lamps, but he found the carbons went to pieces, and he had about reached the conclusion that carbon was an unserviceable material for incandescent lamps. The following year Sawyer and Man invented that beautiful process of theirs, the hydrocarbon treatment, whereby imperfect carbons could be made of uniform structure throughout, as well as another extremely valuable invention in the manufacture of carbons; a method of more effectually disassociating the carbon from oxygen. They had made a large number of lamps in 1878, embodying those two inventions, which became the subject of patents in 1878 and 1879, and being thus patented, they were not open to Mr. Edison, but he had, nevertheless, devised his own method of working; a method of carbonizing; a secret one as appeared from the testimony, not revealed at the time and not revealed even at the present time. His new method of carbonization, according to his general account of it, left the carbon in that condition of porosity in which it came out of the muffle. He especially disavows any suggestion of a process which would deposit unstructural carbon in the pores. Defendants therefore thought they had a right to insist that the term "filament" imported this condition, and that it was by reason of the high specific resistance of the burner, due to that kind of carbon that Mr. Edison was able to secure the high total resistance which he says is essential to the use of a large number of lamps in multiple arc.

In dealing with the question of coiling the burner, Gen. Duncan said that he had omitted to consider one passage in the specification, which had been much relied on by the plaintiff in support of the proposition that it was not necessary to coil the burner. Mr. Edison had said, "I have carbonized and used cotton and linen thread, wood-splints, paper coiled in various ways; also lampblack, plumbago and carbon in various forms mixed with tar and kneaded so that the same may be rolled out into wire of various length and diameter." But he (Gen. Duncan) thought that the subsequent paragraph, dealing with the question of the distortion of the filament while being carbonized, showed conclusively that Mr. Edison did intend, under all circumstances, to coil the carbon. It went without saying that these limitations sought by defendant to be imposed upon the second claim were not accepted by the plaintiff. It was absolutely essential to the success of their contention that those limitations should be removed from the patent. The defendant did not coil its burners, two of its carbons were below 100 ohms resistance, and it made use, moreover, of a carbon treated by hydrocarbon process and having its resistance greatly reduced thereby. He thought that contention was out of all harmony with the views expressed by Mr. Edison, by the plaintiff, the Edison Company, and by their respective counsel, when they were urging before the Patent Office, from December, 1880, down to 1887, the divisional application for a patent applied for in December, 1880. The only difference between one of the claims of this divisonal application and the second claim of the patent in suit, as interpreted by the plaintiff, was that the word "flexible" had been introduced into the claim of the application; but this was mere surplusage, for it was in evidence and had been insisted upon by all plaintiff's experts, that flexibility was an inherent condition of a carbon filament. They had been informed in the court below by counsel that this divisional application had been permitted to lapse. For a long time they had been trying to ride two horses, but the courses of the two animals had become so widely divergent, that they had been compelled to leave one and rest their case on the other. They had chosen now to come into court and say that the patent in suit was for putting an incandescing carbon filament into an all-glass globe from which the air had been exhausted, but for years they had insisted in the Patent Office that no such construction was possible for the patent in suit. Which was the better judgment of those gentlemen? That first expressed, when they thought they could secure a patent that in terms would cover the very ground they desired to cover, or the interpretation which had been picked up as a forlorn hope, and on the possible chance of success presented to this court?

There was another aspect of that divisional application which defendants desired to urge upon the attention of the court.

It afforded an adequate explanation of the long delay of the plaintiff to bring suit against the United States Electric Lighting Company. They had no faith that the patent in suit could be interpreted to hold the defendant's lamps, but they had hoped that they might, on the pending application, secure a patent which would hold defendant's lamps to be an infringement, and failing in this they had said: "Now the only chance we have is to go to the court and seek to put upon patent No. 223,898 an interpretation which we have disavowed over and over again before the Commissioner of Patents." In the Circuit Court the reference to this divisional application had been brief. The court had said: "It is of but little import what Mr. Edison or his solicitor may have thought about the meaning of the claims during the pendency of the application for a subsequent patent. There are many adjudicated cases where the inventor builded better than he knew; where a patent has been sustained for an invention, the full significance of which was not appreciated by the inventor when he made it." It did not seem to him that that quite met the case. The question was not whether Mr. Edison had foreseen all the uses of his incandescent lamp, but what had he understood his invention to be? To answer this, resort must necessarily be had to the utterances of the inventor; primarily they were, of course, to go to the patent. If the inventor had failed to make a complete disclosure of his invention, then they had a right to take his other contemporaneous utterances, and when they had gone to this divisional application of Mr. Edison, they found, that year after year language had been used that was wholly at variance with the construction now insisted upon by the plaintiff.

General Duncan said he would next turn to the consideration of the prior state of the art. It was logical to determine so far as practicable the exact date of the invention of the patent in suit. He contended that this date could not be earlier than October 21st, 1879. The patent seemed to claim that Mr. Edison's invention consisted largely in the use of a peculiar form of carbon to which he had given the curious name of "filament." Long before that date many things had been done in the art of electric lighting and in the kindred arts, to which it seemed profitable to call the attention of the court. One of these notable things was the Geissler tube. It showed the use of a globe made entirely of glass and highly exhausted, and also means for conveying an electric current into the vacuum, consisting in the use of fine platinum wires sealed by fusion. It also showed that where an increase of resistance was desired for securing a larger amount of light, it could be done by diminishing the cross-section and increasing the length, and by coiling the increased length in a spiral. Another important contribution was the radiometer of Professor Crookes, consisting of a glass globe hermetically sealed at all points, into which had been introduced a spiral of fine platinum supplied with an electric current by means of platinum wires sealed into the glass by fusion. It was in every sense of the word an electric lamp, although it had not been employed for the general purpose of illumination; that was not the problem Crookes had been aiming to solve. They had repeatedly been told by gentlemen on the other side, that the very essence of a filament was a high ratio between resistance and radiating surface. If that be so, then the British patent of King of 1845, which had instructed a person to take a very small pencil of carbon rather than a large one, had given instruction to select the form of carbon that would give a relatively high relation of resistance to radiating surface. He did not think his friends on the other side had the right definition of a filament, but if they were right, then the whole philosophy of the filament had been revealed in the King lamp. He would next consider for a moment certain patents granted to Mr. Edison in France in 1879 and in this country in May, 1880, upon an application filed in April, 1879. They were upon Mr. Edison's platinum lamp. As this invention had played a very important part in the general discussion, he trusted that it would receive full consideration from the court at the final discussion. In those patents he had said that in order to use a large number of lamps in multiple arc, the resistance must be very high, and that this could be secured by a small cross-section of wire of great length, and in order to use this great length he had coiled it up on a bobbin. The lamp was essentially like the lamp of the patent, except that in one case platinum is used for the burner and in the other case carbon. In both cases they had the all-glass globe, the high exhaustion and the fine platinum wires for carrying the currents into the interior of the globe through the walls. In April, 1879, Edison had applied to the Patent Office for a patent upon his platinum lamp. He did not obtain it until May, 1880, and then with a very broad claim, more comprehensive than any claim in the patent in suit, even under the interpretation insisted upon by the plaintiff. If Mr. Edison had created a revolution in the art, or a new art, which of these patents had accomplished that result? Was it this patent of manifestly narrow limitation, in which *coiling* was embodied as a necessary element, or was it this broader patent on the platinum lamp, wherein he had described, with greater fullness than in the patent in suit, the advantages of high resistance and small radiating surface; of a globe all glass and highly exhausted, and had then taken a claim acknowledged by their adversaries to be more comprehensive than any claim of the patent in suit?

In a caveat which Mr. Edison had filed in the Patent Office in 1879, during the pendency of the application for the patent in suit, he had said: "The object of this invention is to produce carbon conductors of high resistance to produce the electric light by incandescence." He then tells us that if he takes retort carbon, and pulverizes it, and mixes it with non-conducting substances, and molds it into the form of a burner, that burner will be a "carbon conductor." Now that was precisely what Lane-Fox had described in his British patent, published before the date of Mr. Edison's invention of the thing covered by the patent in suit. Lane-Fox had made a burner of that description, of small cross-section, having a high resistance, and enclosed in an all-glass globe from which all gases capable of attacking the carbon had been excluded.

After referring at considerable length to the work done by Sawyer and Man and the experiments of Dr. Adams, of Boston, General Duncan said that defendants felt justified in contending that at the date when Mr. Edison professed to have made the invention of the patent in suit, October 21, 1879, it could not have been patentable to anybody to employ carbon for making an incandescent lamp; to use a high vacuum to protect the carbon from destruction; to use a globe entirely of glass for preserving a high vacuum, nor to make use of leading-in wires of platinum sealed into the glass. It was perfectly well known, moreover, that lamps must be arranged in multiple arc in order to secure a wide distribution, and that to secure that result the burners must be of high resistance and small cross-section. It was perfectly well known too that when two pieces of glass were sealed together with cement and the vacuum deteriorated, the remedy was to fuse the glass together. It was not competent at that time for Mr. Edison to claim an electric lamp having as a burner a continuous conductor in an exhausted glass enclosing globe. He also contended that it was not open to Mr. Edison on October 21, 1879, to claim an electric lamp having a continuous carbon conductor reduced to filamentary size, and introduced into an all-glass and exhausted globe. That was simply the question of putting one piece of carbon in place of another piece of carbon, or of putting a piece of carbon in place of platinum. The best testimony which supported that proposition had been Mr. Edison's own statement, which was in evidence. It was simply a question of the substitution of material. Mr. Edison's doubt was not whether carbon substituted for platinum would remain sufficiently stable for commercial purposes. It was whether he could make a filament of carbon sufficiently homogeneous. There lay the difficulty; there was the field for invention. He had solved that problem, partially by a compromise. He could not get down to a sufficiently small cross-section, and therefore had been obliged to content himself with a larger cross-section, and then to get the requisite resistance he had taken a longer length of the larger size and had disposed of the surplus radiating surface by coiling up the extra length.

It would be interesting if time permitted, to examine the testimony of Mr. Edison and his coadjutors as to the utility of the several materials named in the patent from which to construct a burner. Their testimony had completely refuted the proposition that any invention disclosed in the patent could have had any favorable effect upon the art. He thought Judge Wallace had been in error in holding, as he had done in his opinion, that lamps would and did succeed which were made solely under the patent in suit.

There were grave criticisms which might be passed on the patent in suit on the score of its ambiguity. It went without saying, upon a simple inspection of the patent, that the emphasis of the second claim lay in the presence of the term "filament"; a term which ought to have been defined, but which had been left in such a condition that it was impossible to know what was meant. General Duncan then quoted at length from the decisions of Judge Wallace, of Lord Frye of the English Court, and of the German Court of Appeal, severely criticising the ambiguity and the uncertainty of the language of the patent. He contended further that the description was not so complete, clear and exact as to enable any one to make a practical lamp. Prof. Thomson, who has had large experience, had said that one could not, by following the description of the patent, and without resort to other processes and inventions not known to the art at the date of the patent, make a practical lamp, and had given his reasons in full. Then Mr. Howell had been called by the plaintiff, and had said that he had made lamps without any difficulty, and had told how he did it, and it had proved that Mr. Howell had resorted to a method of carbonization not known to the art at the date of the patent. He had found it necessary indeed, to use the very method of carbonization which Mr. Edison in January, 1880, had been working in secret, and had not revealed in the specification now before the court. In other words, the Edison Company when they had been put to the crucial test as to whether or not the description in this patent was sufficient, had come into court and had confessed that they could make good lamps under this patent, if permitted to employ methods of carbonization not known to the art at the date when the patent issued.

"PARENT" COMPANIES AND LIGHTING COMPANIES—KANSAS CITY ELECTRIC LIGHT CO. vs. THOMSON-HOUSTON ELECTRIC CO. ET AL.

THE petition of plaintiff, filed in the Circuit Court of Jackson county, Missouri, June 7, 1892, sets forth, that under and by virtue of a certain contract entered into on the 14th day of Nov., 1881, by and between the American Electric Company, predecessor of the Thomson-Houston Electric Co., party of the first part, and J. S. Chick, trustee for J. W. L. Slavens, *et al.*, predecessors of the Kansas City Electric Light Co., party of the second part, said first party licensed said second party for the sole and exclusive use in the counties of Jackson, Missouri, and Wyandot, Kansas, of all apparatus manufactured or controlled by virtue of the patents then owned or controlled, or *to be* acquired, owned or controlled by the party of the first part. The petition recites that one of the most valuable patents thereby conveyed was that covering the device known as the "Thomson Automatic Regulator," and that notwithstanding its obligations under said contract to sell said device as well as all other apparatus in said counties only to or through the party of the second part, the Thomson-Houston Electric Company did license the Fort Wayne Electric Company to manufacture under said regulator patent, and that the Fort Wayne Electric Company, upon the authority so given, sold to the American Electric Light Company, of Kansas City, a plant of six hundred arc lamps equipped with said regulator. On account of this breach of contract, the plaintiff asks the court to enter judgment in its behalf against the defendants for damages aggregating $210,000, to decree that an account be taken of losses and damages sustained by plaintiff by reason of the premises; that said American Electric Light Company of Kansas City, be restrained from using said regulator in said counties; that the defendants, the Thomson-Houston Electric Company *et al.*, be forever restrained and enjoined from selling any of their machines with said regulator attached in said counties to any person or corporation excepting plaintiff; that said American Electric Light Company, of Kansas City, be enjoined from purchasing said regulators, and that the plaintiff have any other and further relief to which in equity and good conscience it may be entitled.

The progress and result of this suit will be noticed with great interest by many lighting companies who will be glad to learn what degree of protection they possess in the use of patented devices purchased under contracts similar to that sued upon by the Kansas City Electric Light Company.

GILLETT vs. WESTERN UNION TELEGRAPH CO.—CONTROL OF TELEPHONE PATENTS.

THE suit of Gillett *et al.* vs. the American Union Telegraph Company, came up for trial on Thursday last before Judge Wallace and a jury in the United States Court in this city. In 1880, Webster Gillett, one of the plaintiffs, sold a controlling interest in a patent for a long-distance telephone transmitter to the defendant company, under a contract stipulating that neither party should sell its interest without the consent of the other, and that the defendant company should use its best endeavors to establish a profitable business in making and selling the patented telephones, paying to the complainiant a stipulated royalty on each instrument. The defendant company afterwards transferred all its property and franchises to the Western Union Company and as plaintiff alleged, thereby placed itself in a position whereby, by reason of the existing contracts between the Western Union and American Bell Companies, it became totally incapacitated from carrying out its contract with the plaintiffs. Damages of $100,000 were alleged to have been sustained by reason of this alleged breach of contract. After hearing plaintiff's evidence, Judge Wallace decided that no title in the patent had passed to the Western Union Company, by virtue of the consolidation proceedings, and that plaintiffs had failed to make sufficient affirmative proof that any actual damages had been sustained, and he directed the jury to bring in a verdict for plaintiff of six cents damages.

THE OLD WESTERN UNION—AMERICAN BELL SUIT.

A SPECIAL dispatch of June 2, from Boston says: "A $12,000,000 suit was dropped from the United States Circuit Court to-day, but it was done in such a manner that it can be renewed at any time. It was the suit of the Western Union Telegraph Company against the American Bell Telephone Company for alleged breach of contract. The suit was brought to compel the defendant to transfer to the plaintiff one-fifth of the shares of the capital stock of numerous corporations operating telephones and exchanges throughout the United States, and also one-fifth of the dividends of the companies and one-fifth of the sums paid the defendants for license to connect telephone exchanges, and one-fifth of the bonds and securities received for the licenses for telephones. The gross amount claimed by the telegraph company is about $12,000,000. The contract which forms the basis of the suit was made Nov. 10, 1879, between the American Speaking Telephone Company, the Gold and Stock Telegraph Company, the Harmonic Telegraph Company, the Western Union Telegraph Company who are the present plaintiffs, and the National Bell Telephone Company, which was the predecessor of the present defendant. The Western Union Company controls the stock of the companies named as plaintiffs, except the Harmonic, and the contract was an agreement which was intended to settle a war between the telephone companies, and also settle the titles of the parties.

The contract gave the defendant the right to conduct the general business of the telephone companies, and a right to use the Gray and Edison patents, which were owned by the plaintiffs. By the contract the defendant was to pay the plaintiffs 20 per cent. of all sums received for rentals and royalties. The question raised in the case was whether the 20 per cent. was to be returned upon all sums received or only on profits made."

Letters to the Editor.

STORAGE BATTERIES IN PARIS CENTRAL STATIONS.

In the May 18 number of your estimable journal we read under the caption "Storage Batteries in Central Stations in Paris," a long dissertation in favor of the accumulators made by the Société pour le Travail Electrique des Metaux. According to this article they are the only ones used both in central stations and in various private installations near Paris. The self-confidence of the author of this article is surprising. Permit me to give the facts in the case.

We will not dwell on details owing to the fact that the suits which we have brought against all the infringers of the patents of Faure-Sellon-Volckmar are now on trial before the Correctional Court of the Seine, and we consider the Société pour le Travail Electrique des Metaux one of our worst infringers.

Competing with the accumulators of this last-named Société, we have our makes installed in the stations of the Société Popp. Moreover, we inform you—and this has much weight in judging the satisfaction which our products give—that M. Popp has just asked us for and obtained a license to make them.

Besides, several very important companies and firms of Paris and France have also negotiated for licenses from our company, notably "La Société Electrique à Bruxelles" (Julien), "La Société Betts & Cie, of Carcassone, la Société des Accumulateurs Tommasi, de l'Atlas, Tudor, the firm of Jarriant, in a word, all the houses which do a good commercial business. These attestations place strong doubts upon the truth of the information furnished your esteemed contributor during his stay in Paris.

As to the assertion that the accumulators of the Société pour le Travail Electrique des Metaux, having shown an efficiency of 90 per cent. in the tests made by the French Government, it comes from interested parties. Nothing has been published officially in regard to this matter, but we can tell you that it comes to us from an official and absolutely disinterested source that they do not bear any comparison with the Faure-Julien type of accumulators.

The electric traction which has been accomplished by us with success upon many of the street car lines of Paris, still awaits its practical realization by the Société du Travail Electrique des Metaux, who are still at it in Paris, after an attempt of three months without turning out a single vehicle to the public. We consider, sir, that you will be too anxious for the truth not to grant us space to rectify what we should have liked to explain at length.

THE AUTHORIZED MANAGER,
Société Francaise d'Accumulateurs Electriques
"Faure-Sellon-Volckmar."

PARIS, June 2, 1892.

STORAGE BATTERIES IN PARIS CENTRAL STATIONS.

With regard to the letter from the Société Francaise d'Accumulateurs Electriques "Faure-Sellon-Volckmar" of Paris, I would state that it was not my intention to imply in my contribution to your journal of May 18th, on the subject of "Storage Batteries in Central Station Work," that the accumulators of the Société Anonyme pour le Travail Electrique des Metaux as described by me were the *only* accumulators in use in Paris. My object was to state as briefly as possible a few interesting facts regarding a system which is being worked successfully on a very extensive scale and, as far as I could learn, more extensively than any other system in Paris. At all the stations of the Société Popp, I saw only cells of the large type as described. I was informed that they had a few of another type which, however, were being rapidly replaced by those of the Société Anonyme. It would have been very interesting to know how many and what sized cells of the Faure-Sellon-Volckmar pattern are now being used by the Société Popp and also in other parts of Paris. The fact that certain companies have *asked for* manufacturing licenses does not appear to me to effect the main object, namely, that of actual successful results obtained from the practical working of large cells on a large scale, such as is demonstrated by those of the Société Anonyme pour le Travail Electrique des Metaux. If the Société Francaise d'Accumulateurs Electriques Faure-Sellon-Volckmar have at the present time installations on an equally extensive scale and working with equally or more successful results, I can only state that any particulars as regards these practical results would be read with the greatest interest by readers of your journal, myself included.

As regards the ninety per cent. efficiency obtained by Government tests at Toulon, I have this statement over the signature of a responsible authority. Over the same signature I have the statement that the cells of the Société Anonyme, etc., have lately been selected after repeated trials in preference to all other types on a tram car line in Paris. I have every reason to believe the type of cell as manufactured by the Société Anonyme, etc., in Paris, has not fallen out of favor since my visit, from a letter, lately received in answer to some inquiries, wherein it is stated the output at the works at St. Ouen has considerably increased of late.

Now, as regards the questions of patent litigations, this is the chronic disease of every accumulator company which has ever done any business and is also outside the present question, namely, actual working results on a large practical scale. Apart from the patent-right question (which let us all sincerely hope will be decided before the main "bones of contention" become public property), I can only say that if my humble statements can be the means of eliciting from other companies facts proving the existence of larger and superior systems showing equally good or better results than those of the Société Anonyme, etc., of Paris, I shall have at least afforded some assistance in obtaining some important electrical facts of the utmost interest and value.

S. C. C. CURRIE.

NEW YORK CITY.

LEONARD'S NEW THREE-WIRE SYSTEM.

In your issue of June 15, there appeared a letter from Prof. Elihu Thomson, stating that there was nothing new in the three-wire system described by me in your issue of June 8, and claiming that all the results obtained by my system had been previously obtained by himself and Mr. E. W. Rice, Jr. In support of his statement, Prof. Thomson refers to his patent No. 360,125, of March, 1887; Mr. Rice's patent No. 460,364, of September, 1891; patent to Thomson and Rice No. 468,123, of February, 1892; and patent to Thomson No. 468,122, of February, 1892.

Prof. Thomson states that I did not distinctly claim the new three-wire system as my invention, but left the reader to infer this. I certainly intended to claim it, and my patent No. 476,544, of June, 1892, which covers the invention, leaves no room for doubt on this score.

Regarding the patents Prof. Thomson names, careful examination will show that there is no anticipation whatever. Prof. Thomson's patent No. 360,125 contemplates the use of a motor-generator which takes the surplus energy from one side of a three-wire system and transfers it to the other. If this motor-generator could be operated absolutely without loss the method would be of value, but any loss due to field excitation, friction, heating of armature, etc., is fatal, which Prof. Thomson clearly recognizes in his patent, when he says:

> "It is essential that the resistances of the windings A be so low as to be negligible and that their opposition to passage of current, under normal conditions, be due to counter-electromotive force solely."

Fig. 6 of the patent to which Prof. Thomson refers, shows a storage battery, which is connected rapidly, first to one side and then to the other side of the system, so as to receive a charge from the side of high E. M. F. and deliver it instantly to the low side, the object and result of which is entirely different from my use of the battery.

Mr. Rice's patent No. 460,364—the first claim of which is quite broad—has the fatal weakness of being inoperative. Through a curious error, it is assumed in the specification that to convert the compensating dynamo from a generator to a motor, its field must be reversed, and for this purpose its principal winding is a series winding so that, when the current in the neutral wire changes in direction the field of the compensating machine reverses. Following is a quotation from the specification:

> "If L be the lightly loaded side, the current flowing in D′ (the series winding) will be in the same direction as S′ (the shunt winding) and increase the initial excitation of the field, *so that a reversal of the field will occur* and the equalizing machine, becoming a generator, will deliver current to the heavily loaded side, drawing the necessary power from the main driving shaft."

The specification is very hazy in parts and seems to give indication of serious doubt in the mind of the inventor of just what will occur in the neutral wire under changes of load; but the *reversal of the field* is emphasized several times as an essential feature and is claimed distinctly in claim No. 8, which reads, as follows:

"The combination of a multiple series distribution system with an equalizing machine, connected in shaunt around one of the multiple arc groups and coupled mechanically with the main generator, *said machine being so wound that its field is reversed according as the shunted side has the lighter or heavier load*, thereby causing it to act both as a motor and generator, as set forth."

It seems impossible that any one familiar with dynamos and the three-wire system should seriously propose this method of operation, for evidently if we reverse the field there will be a time when the field will be reduced to zero and the dynamo will produce no E. M. F. The neutral wire will then be connected to the outside wire by the short circuit of merely the armature resistance and all the lamps on that side of the system will be short-circuited and the lamps on the other side will be exposed to the full pressure of the larger generator, which, being double the E. M. F. of the lamps, will burn them all out instantly.

As regards the other two patents, which were issued last February, they are very narrow in their scope and cover methods of shifting a dynamo *acting as a motor only*, from one side to the other of the system. A change in the potential of the neutral is caused to actuate an automatic switch, which transfers the motor from one side to the other. The best relays for such a purpose require 2 volts change in pressure to actuate them. A change of 2 volts in the potential of the neutral occasions a change in the E. M. F. on the lamps of 4 volts, as it is added to one side and substracted from the other. Hence, the operation of a switch, such as this, would cause frequent change of 4 volts—or about 4 candles—upon the different lamps in any customer's place, which would not likely be considered as an "improvement" on the method I employ, which necessitates a constant potential on the neutral.

Those practically familiar with the three-wire system will appreciate that a constant potential on the neutral, throughout the entire system, is essential for successful operation and any deliberate change in the potential of the neutral, such as these four patents contemplate, seems to carry one back to '83, when the last of such methods was abandoned, in the shape of the old house changing switch.

"The proof of the pudding is in the eating." A central station plant has been operating under my system for over six months, at Charlestown, W. Va., under peculiarly difficult conditions, as to distribution, and has had no expert attention from the day it started, and has operated perfectly in every way. If the same is true of the methods patented in the patents which Prof. Thomson refers to, no information has reached the public to that effect, although I am aware that various experiments in this line have been tried at Bridgeport, Conn., with a view to avoiding the necessity of using the Edison patent, which the Bridgeport Company is infringing by the use of an Edison three-wire system, installed by the Thomson-Houston Company.

H. WARD LEONARD.

NEW YORK, June 17, 1892.

BRAKING CARS ELECTRICALLY.

I NOTICE in your issue of May 11, a description of a method of stopping electric cars, devised by Mr. Sidney H. Short. I beg to call your attention to the fact that this method is by no means new, but dates back as far as 1888, where it was employed in the cars of the Observatory Hill Passenger Railway in Allegheny, Pa. Here no special device was employed, the ordinary connection of the motors being such, that by simply throwing the reversing switch, the car would act as you describe. The discovery of this action was a chance one, it being first noticed where a car refused to run down a steep grade with the brakes off. After searching in vain for the cause, it was found that the reversing switch was set wrong, and upon changing it, the car immediately started off at a good speed. The reason for this action was soon worked out and, from that time on, it was frequently used in emergencies and in wet weather, in descending the steep grades with which this road abounds. I have thought the above might prove of interest to your readers.

JOHN S. CONWER.

BREMEN, GERMANY, May 21, 1892.

STRENGTH OF THE McINTIRE JOINT.

REFERRING to Mr. F. W. Jones's very valuable article on "Breaking Strains of Various Joints in Hard Drawn Copper Telegraph Wire," in your issue of June 1, I note that mention is made therein of the McIntire sleeve, 4½ inches long, not soldered, three full twists given in making the joint. Mr. M. M. Davis, the gentleman making the various tests of joints, gave the McIntire sleeve only three full twists, whereas he should have given the sleeve at least four and a half or five full twists, to make a perfect torsion joint; as a sleeve connector four and a half inches long will shorten up with proper twisting one-half inch in its length, thus bringing the two wires and sleeve into intimate contact, and with the effect of hardening the sleeve and making it rigid, thus making a perfectly strong and substantial joint and one giving the best of electrical contact of the wires and sleeve.

Mr. Jones's Company (the Postal Telegraph-Cable Co.) were among our first patrons, their first order being placed in June, 1886, for twelve thousand sleeves for B. & S. hard-drawn copper wire, after they had made the necessary tests as to the strength and conductivity of our joints; and from that date to this the Postal Company have used about one hundred thousand of the McIntire patent connectors for hard-drawn copper wire, and never made any complaint as to the wires pulling out of the sleeves in actual practical line work. I would be greatly pleased at any time to test the McIntire patent connectors for any size or kind of wire in comparison with any or all of the quite numerous varieties of joints mentioned by Mr. Jones in his article, as to their breaking and electrical qualities.

The McIntire patent connectors have been a commercial article for the past six years, being used by all the leading telephone, telegraph, and electric light companies in the United States, Canada, and Europe, and we have as yet to receive our first complaint as to any unsatisfactory or defective working of them.

C. H. MCINTIRE.

NEW YORK, June 6, 1892.

SHORT GEARLESS MOTOR PERFORMANCES.

So much comment and misconception has been occasioned by an engraver's error in the published account in THE ELECTRICAL ENGINEER of April 13, of Professor Short's paper, read this spring before the Chicago Electric Club, that it has seemed necessary to give the correction as wide a circulation as the paper received.

The error referred to was in numbering the ordinates (abscissæ) of the curve, page 387, Fig. 3, giving the horizontal effort and speed. As this curve appeared in the printed article, the ordinates (abscissæ) were numbered 500, 1000, 1500, etc. As it appeared on the blue prints distributed by Professor Short when reading his paper, they were numbered 50, 100, 150, etc., with the final 0 of 500, 1000, 1500, etc., being clearly crossed out. It is not surprising that the curve, as it appeared in print, occasioned comment, as, according to it, a 20 h. p. gearless motor would have handled with ease a fair-sized freight train.

We would be pleased to have you give this correction publication at your earliest opportunity.

THE SHORT ELECTRIC RAILWAY CO.,
CHAS. F. UEBELACKER,
Engineer.

CLEVELAND, O., JUNE 11, 1892.

[While we regret very much that such an error should have crept into the engraving, we must be held entirely blameless in the matter, as the engravings were furnished to us by the secretary of the Chicago Electric Club, and we were thus justified in assuming them to be correct.—EDS. E. E.]

ELECTRICITY IN A MODERN OFFICE.

"THERE is a somewhat ancient proverb to the effect that the shoemaker's wife is always the worst shod, but it hardly applies in electrical circles. The snug little office of an electrical newspaper manager in this city is a very good illustration of the manner in which the new agent can be made to fill many rôles, and of the practical use to which the initiated immediately put their obedient servitor. Over his desk hang convenient incandescent lights. Behind him stands a well-worn phonograph, to which he thinks nothing of dictating fifty or a hundred letters a day. This is run as usual by a little electric motor deriving its current from a storage battery, which in turn is perennially refreshed by four ordinary gravity batteries. The whole outfit is small and inconspicuous and requires no attention for months together. At one side of the desk stands a little fan motor, also run by small storage batteries, and ready at any instant to deliver a cooling breeze. Right in front of the manager is a miniature switchboard and "buzzer" box and a portable upright telephone. With this he has instantaneous communication with eight different departments of the office, and can give instructions or receive information on any point by the mere insertion of a plug in the board. To-day all this is certainly an exceptional equipment for a business office, yet there is no reason why it should be. It is inexpensive and gives very little trouble, yet promotes health and economizes time in a way that 'must be seen to be appreciated.'"

The above paragraph is reprinted from the New York *Evening Post* of June 11, 1892, and refers to one of the new offices of THE ELECTRICAL ENGINEER at 203 Broadway, New York.

MANCHESTER, MASS., ELECTRIC CLUB.

THE MANCHESTER ELECTRIC CLUB held a meeting at the board of trade rooms last week, and in accordance with the constitution and by-laws adopted at a previous meeting, proceeded to effect a permanent organization by the election of the following officers for the ensuing year: President, G. I. Hopkins; vice-president, J. Brodie Smith; secretary, Herbert W. Eastman; treasurer, E. J. Burnham; executive committee, G. I Hopkins, ex officio, chairman, E. M. Bryant, G. A. Corson, W. H. Fairchild. The club will begin its work at once.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JUNE 7, 1892.

Accumulators :—

Secondary Battery Plate, E. C. Paramore, 476,483. Filed Sept. 2, 1890.

Consists of a porous cup containing a grid consisting of a sheet divided into leaves and having active material surrounding it.

Conductors, Conduits and Insulators :

Metallic Circuit Cable, C. E. Jackson, 476,464. Filed Nov. 12, 1891.

An insulated conductor with two helically wound metal strips, the second being so arranged as to cover the space between the turns of the first and the convolutions of each strip being separated.

Electric Cable, W. R. Patterson, 476,484. Filed Oct. 29, 1891.

Employs a core of insulated conductors and a metallic sheath having interior longitudinal ribs in contact with the core.

Conduit for Electric Railways, W. Bradley, 476,603. Filed June 22, 1821.

Has for its object to provide a conduit which shall afford but little opportunity for the entrance of foreign substances, and shall be convenient of construction and economical in use.

Insulator Bracket, T. H. Brady, 476,604. Filed Apr. 9, 1892.

Galvanic and Thermo-Electric Batteries :—

Electric Battery, R. P. Osgood, 476,296. Filed Jan. 18, 1892.

Employs two perforated copper plates on opposite sides of the cell and connected together; the outer plate immersed in a solution of blue vitriol and the inner in an acid solution.

Galvanic Battery, M. M. Clark, 476,733. Filed Dec. 26, 1888.

The invention consists in mounting the carbon plates in the lead cover, in providing a lead binding post upon the cover and a wooden ring for supporting the cover upon the jar.

Distribution :—

Electric Lighting System, A. Sechrist, 476,422. Filed Dec. 1, 1891.

Provides means for turning incandescent lamps on or off from a distance.

System of Electric Lighting, T. A. Edison, 476,527. Filed Aug. 7, 1882.

Consists in arranging the lamps in separate cross or multiple arc circuits, each controlled independently by a circuit controller.

System of Electrical Distribution, T. A. Edison, 476,529. Filed Oct. 10, 1883.

Has for its object to protect generators, etc., from lightning by means of two or more metallic conductors, translating devices connected with them in parallel and a ground connection from each conductor through a resistance.

Electric Lighting System, T. A. Edison, 476,531. Filed Apr. 26, 1881.

Employs three or more derived circuits, each containing an independent translating device, a magnet and armature in the first branch normally holding the second branch open, but closing it when demagnetized; a magnet and armature in the second branch holding the third branch open and a device for holding the armature against its contact when retracted.

System of Electrical Distribution, H. W. Leonard, 476,544. Filed Dec. 28, 1891.

Relates to series multiple distribution in which a compensating conductor is connected between the translating devices in series, and has for its object to make such translating devices independent of each other.

Dynamos and Motors :—

Safety Device for Electric Motors, E. Thomson, 476,330. Filed Oct. 16, 1889.

Employs a safety fuse mounted on a heat-conducting support subjected to the heating of the coils.

Dynamo Electric Machine, E. Thomson, 476,331. Filed Oct. 14, 1889.

Has for its object to increase the capacity of the machine and do away with the dead point in the rotation of the usual armature having a single circuit where the phase of current is zero and obtaining uniformity in the resistance to rotation.

Alternating Current Motor, M. J. Wightman, 476,346. Filed Nov. 14, 1888.

Employs an alternating current field magnet and an alternating armature, both supplied with synchronous currents from an external source and a commutator by which the armature coils in half of the magnetic field are cut out of circuit.

Brush Holder for Dynamo Electric Machines and Motors, F. B. Daggett, 476,368. Filed Sept. 8, 1891.

A carbon brush holder and retaining spring.

Electric Motor, D. H. Wilson, 476,347. Filed Aug. 28, 1891.

Has for its object to obtain greater efficiency and greater economy in construction, while occupying less space than is usual in motors of the same horse power.

Electric Generator or Motor, E. A. Sperry, 476,426. Filed Apr. 3, 1886.

Relates to the regulation of the generation of currents in a dynamo or the developing of counter E. M. F. in a motor.

Lamps and Appurtenances :—

Apparatus for Trimming Carbon Points, P. Moses, 476,292. Filed June 25, 1891.

Electric Arc Lamp, E. F. Smith, 476,425. Filed Oct. 5, 1891.

An arrangement by which the carbon feed rod is first lifted to form the arc and then moved toward the point of combustion at a speed equal to the consumption of the carbon.

Electric Arc Lamp, C. E. Scribner, 476,493. Filed Oct. 13, 1891.

Provides regulating mechanism in which a single electromagnet in shunt of the carbons regulates the length of the arc.

Incandescent Electric Lamp, E. E. Weaver and G. B. Manypenny, 476,501. Filed Dec. 5, 1891.

Employs a hollow reflector forming the inner wall of the incandescent lamp for the purpose of enhancing its brilliancy.

Incandescent Electric Lamp, T. A. Edison, 476,528. Filed March 16, 1883.

An incandescent lamp with a plurality of filaments.

Incandescent Electric Lamp, T. A. Edison, 476,530. Filed June 4, 1887. Employs two metal plates connected to one of the leading-in wires and having their surfaces near together.

Electric Arc Lamp, R. H. Thurston, 476,700. Filed Feb. 27, 1892.

Consists in twisting one of the carbons so that its end will form a small angle with the other carbon.

Miscellaneous :—

Electrical Governor, M. A. Replogle, 476,311. Filed Dec. 12, 1890.

Employs a tripodal mercury cup revolving horizontally and having a connection with the middle tube at low speed and another connection with the outer tube at excessive speed.

Electric Chime or Bell, J. H. Hunter, 476,463. Filed Feb. 29, 1892.

Consists of a gong placed near the pole of the magnet and movable under the attraction of the latter.

Electric Magnet, A. D. Ayres, 476,236. Filed Sept. 15, 1891.

Employs a series of coils and divided core armatures bound together and forming portions of particular magnetic circuits, and a commutator so arranged that the combined armatures partake of the action of the series.

Electric Body Wear, R. S. Mears, 476,478. Filed Nov. 27, 1891.

Electrically Controlled Valve, W. B. Fleming, 476,376. Filed Nov. 3, 1888.

Base Ball Game, M. Ullman, 476,334. Filed Aug. 14, 1891.

An electrical toy representing a game of ball.

System of Testing Electric Circuits, C. H. Rudd, 476,317. Filed Nov. 4, 1889.

A system of testing for grounds or weak insulation on arc light circuits.

System of Testing for Electric Circuits, C. H. Rudd, 476,490. Filed Jan. 19, 1888.

Consists of a condenser and telephone connected in the circuit and means for closing the latter from different parts of the light circuit through the telephone and condenser to ground.

Fuse Block for Electric Circuits. E. A. Sperry, 476,570. Filed March 19, 1891.

Electrical Valve Controller, J. V. Stout, 476,578. Filed Dec. 22, 1891.

Machinery for Cutting Coal and other Minerals, L. B. Atkinson, C. W. Atkinson & W. T. Goolden, 476,593. Filed Aug. 8, 1891.

Employs a yoke connecting the like poles of two electromagnets and forming a circular base for swiveling upon a traveling carriage.

Electric Light Mast Arm, J. H. Caldwell, 476,607. Filed June 19, 1891.

Electric Street Lamp Post, T Flaherty, 476,739. Filed March 23, 1891.

Electroplate Attachment, C. Keck, 476,653. Filed Dec. 22, 1891.

Process of and Apparatus for Bleaching by Electrolysis, A. E. Woolf, reissue 11,244. Filed May 5, 1892.

Railways and Appliances :—

Railway Signaling System, F. P. Benjamin, 476,240. Filed Sept. 5, 1891.

A system of automatic electric lock signals.

Trolley Support, S. C. Crane, 476,367. Filed March 11, 1892.

Electric Locomotive, T. E. Adams, 476,437. Filed May 28, 1890.

Relates to means for supporting a motor on the car and for gearing it to the driving wheels.

Switches and Cut-Outs :—

Electric Switch, C. E. Davis, 476,613. Filed Feb. 20, 1891.

Relates to means for preventing reverse rotation of the bar, to novel construction of the binding terminals, and means for insulating the metallic parts on the under side of the base from possible contact with the wall.

Telegraphs :—

Apparatus and System for Compound Telegraphy and Telephony, F. W. Dunbar, 476,618. Filed Jan. 25, 1892.

Has for its object to so connect the apparatus that while the independence of the telegraphic and telephonic signals is maintained no obstruction shall be offered to either currents.

Telegraph :—

Telegraph Instrument, C. B. Carr, 476,730. Filed Jan. 7, 1892.

A combined sounder and relay.

Telephones and Apparatus :—

Circuit for Test-Batteries and Cords of Multiple Switchboards, C. E. Scribner, 476,492. Filed June 1, 1885.

A multiple switchboard testing apparatus consisting of a battery placed in the different pairs of cords and means for determining at any given board whether or not a line wanted is connected.

Keyboard System for Metallic Circuits, J. A. Seely, 476,494. Filed Nov. 15, 1886.

Has for its object to connect the clearing-out annunciator in the circuit of one of the cords so that no current will be sent through the former when a signal of the generator is sent over the line.

Keyboard Circuit for Multiple Switchboards, O. A. Bell, 476,509. Filed Sept. 30, 1891.

Has for its object to simplify the circuit connections and the mechanism of the operators' apparatus.

Microphone, C. Vogt, 476,582. Filed May 27, 1891.

Employs a diaphragm having two recessed contact blocks insulated from each other, carbon cylinders bridging these contacts and provided with magnetic sleeves and a magnet in inductive proximity to the latter.

Magnetic Telephone, C. Vogt, 476,583. Filed Sept. 14, 1891.

Provides means for regulating the distance of the poles from one another.

PROTECTING THE RIGHTS OF MINORITY STOCKHOLDERS—T. C. MARTIN vs. THE W. J. JOHNSTON CO., LIMITED.

A POINT of interest to stockholders in business corporations was decided June 17th by the Court of Appeals in the case of Thomas Commerford Martin vs. The W. J. Johnston Company, Limited.

Mr. Martin, who was and is a stockholder in the W. J. Johnston Co., believing that its affairs were being improperly managed by its president, who for two years has paid no profits except to himself, obtained from Judge Lawrence of the Supreme Court, through Masten & Nichols, his attorneys, a peremptory writ of mandamus requiring the company to exhibit its books to him and to allow him to make extracts or memoranda therefrom. The company resisted the application, claiming that Mr. Martin was not a stockholder; that he had no right in any event to make extracts from the books, but only to inspect them; that his demand was irregular, having been made upon the treasurer instead of the secretary, and that his motives for the examination were improper as he was interested in a rival corporation.

The case was very strenuously litigated by the company, which not only endeavored to obtain a stay of the writ, but also carried it twice to the Court of Appeals. This court has now, finally, held, affirming the decision of the General Term, that the writ was properly issued and that Mr. Martin was entitled to the granting of the application as fully as it was allowed.

Personal.

MR. HENRY W. GOODE has been elected second vice-president of the Northwest Thomson-Houston Electric Co. Mr. Goode has earned a high reputation by his very efficient work on the coast, and this election may be said to mark another stage in his career.

MR. A. A. ALDEN has succeeded M. J. King as electrical engineer of the Bristol, R. I., Electric Lighting Co. Mr. King will hereafter be connected with the Westinghouse electrical interests in Chicago.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

The wise man does not hesitate to spend in advertising what a lawyer would charge for superintending his assignment.—Texas Siftings.

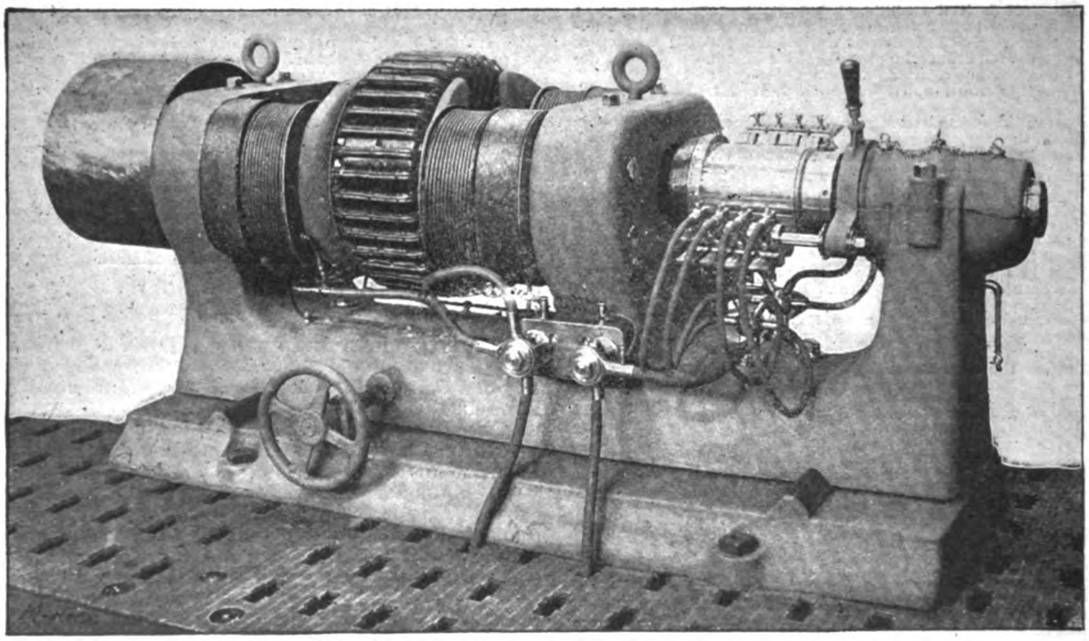
THE BRUSH DIRECT CURRENT INCANDESCENT DYNAMO.

THE accompanying illustration shows the latest improvement in Brush dynamos. It is a new machine of the closed-coil type, with an armature having many bobbins and few turns of wire. The commutator is made of pure copper and mica, and is said to be absolutely sparkless and indestructible.

The frame is cast in one piece, fitted upon V's, which are cast on the bedplate, and is bored out at each end to receive the adjustable self-oiling ball bearings that carry the armature shaft. The field magnets are of soft cast steel, are compound wound, and require only about 3 per cent. of the output of the machine to excite them.

The armature is of the smooth ring type, with iron spacing lugs only. It is made of very thin iron ribbon wound like tape, and has a section about as large as the rest of the magnetic circuit. It contains 36 independent bobbins, whose ends are connected with their corresponding commutator bars by means of wires passing directly from the armature to the commutator outside the shaft. The brushes, about half an inch thick, are made of alternate layers of fine copper wire and thin sheet copper.

The machine, as a whole, is claimed to require less attention than any other in use on account of the care expended upon the design of the commutator, the adjustment of the brushes and the automatic lubricators. It is made in seven sizes, ranging in capacity from 35 to 600 lamps.



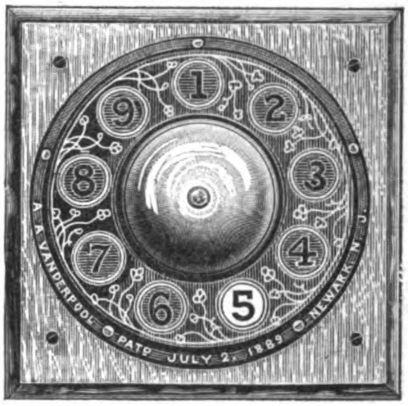
BRUSH DIRECT CURRENT INCANDESCENT DYNAMO.

A CURIOUS WAY OF ADVERTISING.

IN the show window of a store in Wilmington there is a glass case in which is a pivoted Crocker-Wheeler motor with a fan, and about two pounds of feathers. When the motor is in operation it revolves completely around a circle throwing a strong current of air and causing the feathers to fly around in all directions. The crowd about the window is so great that it requires two policemen to keep them away, and as a natural result the dealer is growing rich from his sales of motors. We learn incidentally that the Crocker-Wheeler people are receiving more orders for these pivoted motors than they can fill, and they will undoubtedly have an immense sale. The Crocker-Wheeler Electric Company own the fundamental patent upon this principle as well as the patents on the special devices, and intend to hold the field against all comers.

THE VANDERPOOL SELF-ADJUSTING ANNUNCIATOR.

THE convenient annunciator of which we present an illustration, is the invention of Mr. A. A. Vanderpool, of Newark, N. J. It is self-adjusting, as there are no drops to be replaced, no clockwork or springs, in fact, absolutely no handling of the instrument is required. It can be so constructed as to be flush with the wall or other article upon which it is placed. The numbers or letters if desired are painted on glass discs which are transferable. At the push of the button these become illuminated, as it were, making a most desirable contrast and standing out boldly. The mechanism is very simple, and it is almost impossible for it to get out of order. Mr. Vanderpool would like to arrange with some company for the exclusive manufacture of his annunciator. It can be nicely arranged for from one to seventy-five drops.



VANDERPOOL SELF-ADJUSTING ANNUNCIATOR.

THE ALLIS EXHIBIT FOR THE WORLD'S FAIR.

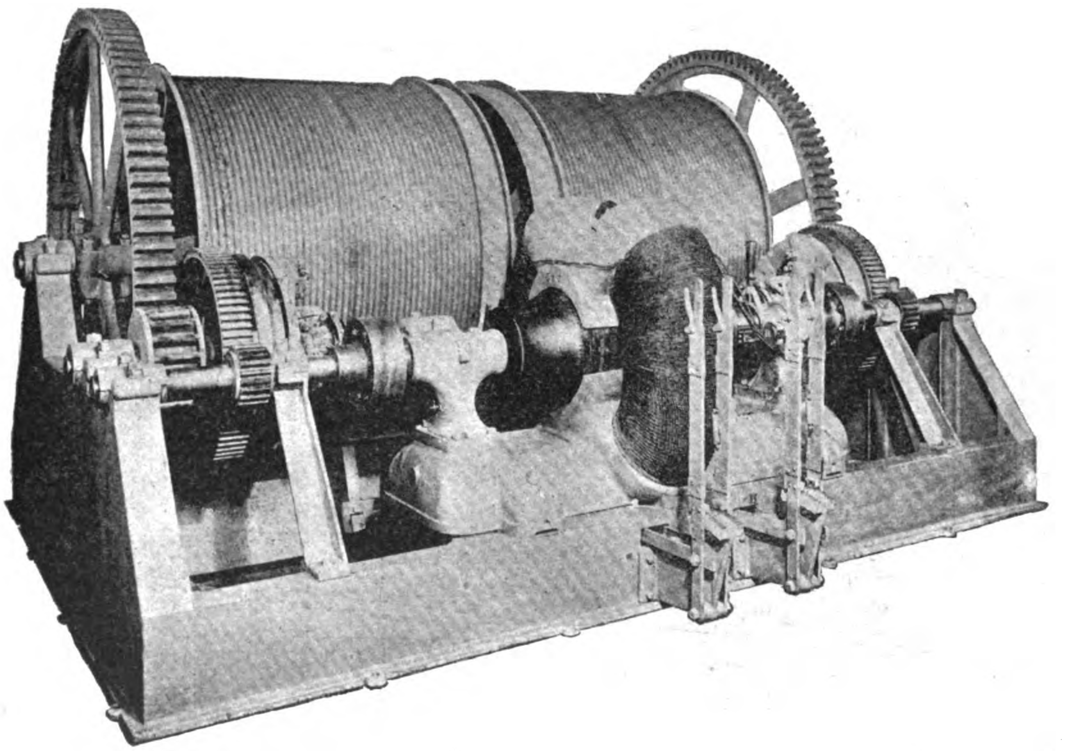
THE chief motive power for the machinery at the Exposition will be supplied by a gigantic engine, to be furnished free to the Exposition by the E. P. Allis Company, of Milwaukee. The engine will be furnished as a part of the company's exhibit, upon a special contract providing that it shall be used for the motive power, and that no other engine of equal size shall be exhibited. It will be an engine of the quadruple-expansion type, and will be of between 3,000 and 4,000 h. p. Compared with this engine the big Corliss that was exhibited at the Centennial Exposition is almost a dwarf. In 1876 the Corliss was rightly considered one of the wonders of the exposition, but its builder rated it at only 1,400 h. p., or less than half of the one being built by the Allis company. The Allis exhibit represents an outlay of $175,000.

THE ELMIRA ILLUMINATING COMPANY.

A NEW station, 66 x 177 feet, with boiler-room and storehouse in addition, is to be erected by the Elmira Illuminating Company of Elmira, N. Y. A 6-foot stack, 150 feet high, will be built and the new equipment will consist of two engines of about 1,500 h. p. capacity, triple expansion, with the necessary condensers; boilers of 1,500 h. p. capacity to carry 160 pounds pressure; shaft 185 feet long with friction clutch pulleys, clutches, floor stands, etc.; an overhead crane of ten tons capacity, a tank and boiler feed pumps, belting, lines, wires. There will be an iron-trussed roof over the machine and boiler-rooms. Work will be commenced immediately. The Elmira Illuminating Company is now owned by the Elmira Municipal Improvement Co. as is also the Elmira Gas Co., the Elmira and Horseheads Railway Co. and the Elmira Water Works Co.

"C. & C." ELECTRIC MINE HOIST.

THE accompanying illustration shows an electric mine hoist recently installed by the C. & C. Electric Motor Co. in a mine at Corbin, Montana. At a rope speed of 400 feet it lifts a weight of 5,000 pounds. There are two drums, each five feet in diameter by forty inches long, intended to run either separately or together, independently geared by two reductions to each end of the motor shaft. The motor pinions are rawhide, and their motion is transferred to the intermediate shafts by means of two Frisbie friction clutches. The motor is 65 h. p. and is reversible. The reversing and speed regulating switch, not shown in the engraving, is placed conveniently near the operator of the four levers shown. Two levers are for throwing the clutches in and out, and two for applying the break-band on the inner peripheries of the drums. The bearings have ample length and the whole machine is substantially and well made. It occupies a floor space of about ten by thirteen feet and has a total weight estimated at sixteen tons.



"C. & C." ELECTRIC MINE HOIST AT CORBIN, MONTANA.

THE ELECTRIC ROAD AT OTTAWA, CANADA.

AT a recent meeting of the Board of Trade of Ottawa, Canada, the operation of the local electric street railway was discussed, and the opinions expressed were decidedly favorable to electric traction.

The electric railway was endorsed as not only having proved to be a great convenience to the public, but as a benefit to the stores along its route, from a business point of view. As one merchant put it "electric railways drew trade to the stores by which they passed." At the close of the meeting, a resolution was passed unanimously, favoring the adoption of electricity as a motive power on the remaining horse railways in the city.

When the electric railway first began running at Ottawa, a year ago, it was confidently predicted by many that it could not be operated successfully during the winter, but the experience of the past year has proved to the contrary, for the road has run on time all winter in spite of heavy snows and severe storms. The system used at Ottawa is the Westinghouse single reduction. The road is 15 miles in length and has 30 cars. The contractors were Ahearn & Soper, electrical engineers, Ottawa, and the same firm is now installing a plant of 30 Westinghouse cars at Hamilton, Ont.

BALL ENGINES.

THE SCHUYLKILL ELECTRIC RAILWAY CO., Pottsvile, Pa., have recently placed a 200 h. p. engine. built by the Ball Engine Co., Erie, Pa. J. C. Hubinger Co., Electric Light Co., of Keokuk, Iowa, have just installed a 300 h. p. cross-compound condensing engine, built by the Ball Engine Co. The engine is giving fine satisfaction. F. R. Dravo & Co., the Pittsburgh representatives of the Ball Engine Co., recently furnished one 50 and one 100 h. p. engine to the Pittsburgh Iron and Steel Engineering Co., Pittsburgh; one 130 h. p. engine to the Moundsville Electrical Co., Moundsville, W. Va.; and one 80 h. p. engine to the Oakland Light and Power Co., Oakland, Md.

ELECTRIC ROADS AT DULUTH, MINN.

THE NORTHERN CAR COMPANY will soon ship, equipped and ready to be transferred to the street car tracks, the first of the new car bodies ordered for the Duluth Street Railway Company. This car is equipped with two 20 h. p. Short gearless motors, and will be placed on the line at the head of the incline and back of the city of Duluth. This line is 1¼ miles long and overlooks the entire populated district at the head of Lake Superior. It is 650 feet above the lake level, and the incline by which it is reached was built at a cost of $250,000. The maximum grade of the road on which these gearless motors will be operated is 4½ per cent.

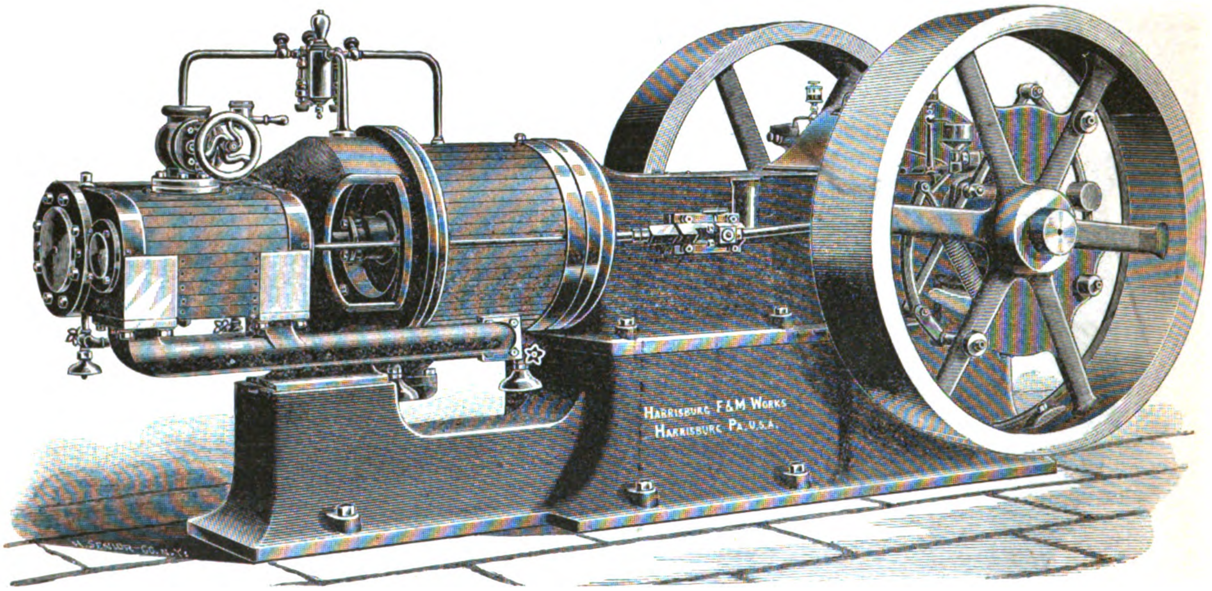
DALLAS, TEX.—Mr. C. O. Harris, the well-known electrician, has recently become connected with the Garrett Electric Machine Works, 474 Live Oak street, Dallas. He has just finished installing a very fine Westinghouse alternating plant at Calvert, Tex., run by an "Ideal" engine of 45 h. p. The streets are lighted by 50 c. p. lamps every 125 feet in the business district, and with 32 c. p. lamps in the residence district every 500 feet. The full 500-light capacity of the plant has been installed. The station is handsomely finished throughout in native woods. Mr. Harris also put in a fire alarm service with 16 stations. Mr. Garrett, his business associate, is also an old electrical man of wide experience, and inventor of the Garrett burglar alarm screen and cash drawer.

THE HARRISBURG IDEAL TANDEM COMPOUND ENGINE.

The Harrisburg ideal tandem compound engine, manufactured by the Harrisburg Foundry and Machine Works of Harrisburg, Pa., and shown in the accompanying illustration, presents some very novel and striking features aside from the self-oiling feature which has made the simple Ideal engine very popular for electric light and manufacturing purposes.

This engine is designed with special regard to high economy, and independent valve motions are provided for high and low-pressure valves, both valves of the piston type. The low-pressure valve is made with an adjustable packing that is claimed to overcome all the objections to piston valves as heretofore manufactured. Another feature in the construction of the engine is the accessibility of the low-pressure piston and cylinder without dismantling the high-pressure cylinder, steam, and exhaust pipe. The connection between the two cylinders is so made that the piston can be moved into this space for examination by simply removing the cylinder heads. The support for the high-pressure cylinder is provided by the extension of the sub-base, which makes a substantial support and avoids any vibration of the cylinder when doing heavy work.

These engines are especially adapted to electric light and electric railway work. The prominent advantages claimed are automatic lubrication, close regulation under varying loads, accessibility to all the parts, perfect equilibrium of the engine when in action, large bearing surfaces, and high economy. A number of these engines have been built and are in operation, giving very satisfactory results. The following agents represent the company: New York, W. R. Fleming & Co., Mail and Express Building; Philadelphia, Frank Johnston, Master Builders' Exchange; Boston, the Post Engineering Co., 180 Summer St.; Pittsburgh, J. A. Robinson, Room 703 Penn Building.



Harrisburg Ideal Tandem Compound Engine.

HARRISBURG IDE AND IDEAL ENGINES.

W. R. Fleming & Co., new Mail and Express Building, New York City, agents for the Harrisburg Foundry Machine Works, have handed us a list of recent contracts for furnishing Ide and Ideal engines. When it is remembered that the sales mentioned below represent only a comparatively small proportion of the United States, and that we happen to know that other agents as well as the factory themselves have each been shipping almost as large a number as is handled through New York City, it is safe to infer that not only is the sale for the Ide and Ideal engines rapidly increasing, but they are doing as large a business as any other engineering concern in this country.

The following list covers the last few weeks' business done by W. R. Fleming & Co. alone, and equals over 2,500 h. p.: One 70 h. p. Standard Ideal engine, one 150 steel horizontal tubular boiler, Edison Electric Light Co., North Plainfield, N. J.; one 60 h. p. Standard Ideal engine, one 60 h. p. vertical boiler, Bar Harbor, Me.; one 30 h. p. Standard Ide engine, one 30 h. p. vertical boiler, McMahon & Wren, Bridgeport, Conn.; four 100 h. p. special direct-connected Ideal engines, Mail and Express Building, New York City, N. Y.; three 100 h. p. Standard Ide engines, Pope Mfg. Co., Hartford, Conn.; one 25 h. p. Ideal engine for steamship service, Harlan & Hollingsworth Co., Wilmington, Del.; one 16 h. p. Standard Ideal engine, steam yacht "Clarion," Newport; one 45 h. p. Standard Ideal engine, Central Stores, New York City, N.Y.; one 55 h. p. Standard Ideal engine, Wild & Williams, New York City, N. Y.; two 225 h. p. Standard Ideal engines, Clarion Mills, Pa.; one 25 h. p. Ideal engine, Weehawken Ferry Co.; one 80 h. p. Standard Ideal engine, one 50 h. p. Standard Ideal engine, Naval Observatory, Washington, D. C.; one 55 h. p. Standard Ideal engine, one steel horizontal tubular boiler complete steam plant, Brazil; one 12 h. p. Standard Ide engine, Whitlock Coil Pipe Co., Elmwood, Conn.; one 55 h. p. Standard Ideal engine, one 60 h. p. Standard Ideal engine, Century Club, New York City, N. Y.; one 150 h. p. special railway Ideal engine, one 80 h. p. special railway Ideal engine, one 55 h. p. Standard Ideal engine, Chillicothe Street Railroad and Lighting Co., Chillicothe, Ohio; one 55 Standard Ideal engine, Hyland Paper Co., Johnsonburg, Pa.; two 60 h. p. Standard Ideal engines, Hotel St. Lorenz, New York City, N. Y.; five 25 h. p. Standard Ideal engines, Pacific Mail Steamship Co., New York City, N. Y.

A FACTORY OPPORTUNITY AT MARION, IND.

Mr. Geo. L. Mason, president of the Inter-State Trust Co., room 705, 925 Chestnut street, Philadelphia, Pa., can give information as to the opportunity to secure a factory building at Marion, Ind., with natural gas, coal and oil advantages. A warrantee deed will be given to a plot of ground 99 by 132 feet, containing a new two-story brick building 40 by 80 feet, substantially built for manufacturing purposes, with natural gas free for light, heat and furnace use. This deed can be secured by any person who agrees to occupy the building for manufacturing purposes and to employ not fewer than 10 men. This matter has, we may say, been brought to our notice by Edwin Harrington & Son, machine tool makers, of Philadelphia, Pa., who have been building special machinery for the Standard Hub Co. at Marion. They say that the factory is a good one, in good location for manufacturing.

STEARNS MANUFACTURING CO.

The Stearns Manufacturing Co., of Erie, Pa., proprietors of the Woodbury automatic highspeed engine, are advised that the Franklin Institute has awarded to the Woodbury the Edward Longstreth medal of merit, stating:

> "The sub-committee after witnessing the operation of several of these engines were impressed with the fact that the skill and intelligence displayed in the design and construction of the engine, had resulted in a machine of handsome appearance, capable of close regulation of speed, smooth in its action, and well adapted for its purposes.
>
> Recognizing the integrity and skill displayed, your committee recommends the award of the Edward Longstreth medal of merit."

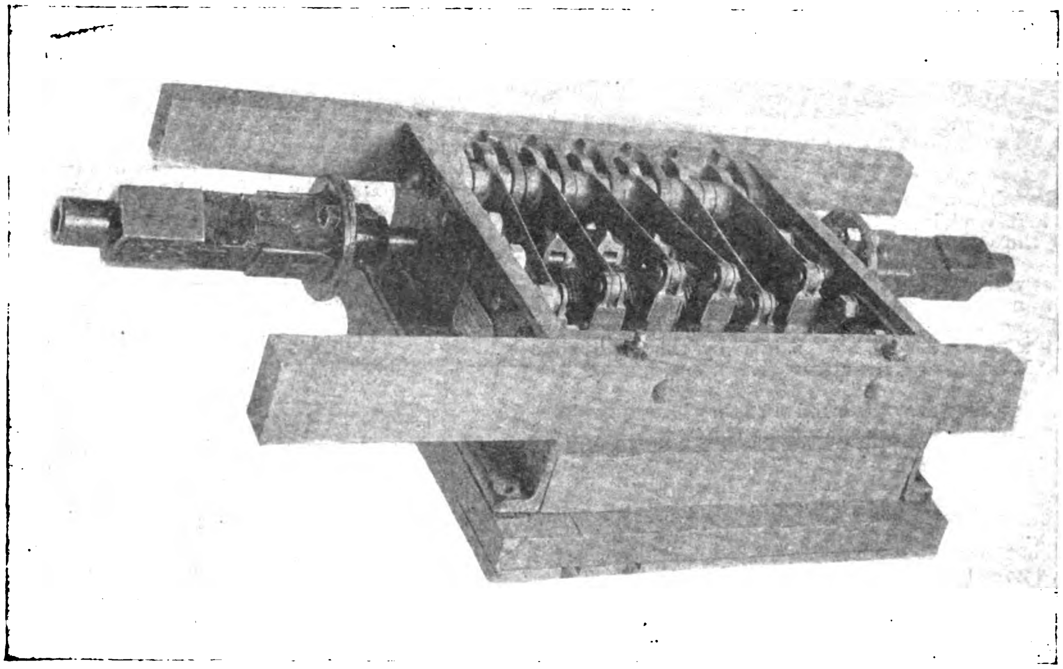
James Christie, Chairman.
J. M. Emanuel.
Spencer Fullerton.
Joseph E. Codman.
Thomas P. Conard.
John H. Cooper.
Adopted May 4, 1892.

Arthur Beardsley, Chairman,
Committee on Science and the Arts.

NEW THOMSON-HOUSTON ELECTRIC RAILWAY CONTROLLER.

The Thomson-Houston Electric Company has for a long time been engaged in experiments, having in view the development of a controller for railway motors that would be an improvement on those now generally used.

It is well known that the regulation of motors by means of a resistance only is decidedly wasteful as well as troublesome. In fact, it involves the consumption of nearly as much energy when the motor is running at a slow peed as when running at a high speed, although the work given out by the motor in the two cases is very different. It simply means that the energy which, in the one case, drives the motor at a high speed is, in the other, partly expended upon the resistance and the remainder, only, is used to drive the motor. It has been customary to modify this method of regulation in well-designed plants by providing, in addition, a device for changing the field magnets of the motor so that the counter-electromotive force for a given speed will be greater and permit, in consequence, the use of a smaller amount of resistance. In some cases these two methods of regulation,—by means of resistance and alteration in field magnet strength,—have been combined in a system of commuting sections of the field magnet coils, by which the coils themselves offer a greater or less resistance to the passage of the current and at the same time have a variable effect on the field magnet strength. In other cases the combination of the two methods has been effected by having a separate resistance external to the motor and then, in addition, providing a switch to cut out a section of the field magnet coils or "loop" as it is often called, or to shunt a portion of the current around them for highest speed.



New Thomson-Houston Electric Railway Controller.

After a long series of experiments the Thomson-Houston Company is now furnishing a controller which, it has satisfied itself, is thoroughly practical, and which at the same time realizes almost a perfect theoretical economy in regulation. In a number of instances where this regulator has been used for some time a saving of thirty per cent. in consumption of current has been effected; and when it is realized that this means a saving at the central station of over three hundred horse power out of a thousand, the great importance of this new device cannot be doubted.

The principle upon which the new controller is based is the shifting of the connections of two motors from series to multiple; so that for slow speed the two motors will be in series, giving in consequence a high counter-electromotive force, that of one motor being in series with that of the other at a low rate of speed; while for higher speed they are connected in multiple, in which condition highest speed and power are obtainable with equal economy.

In the accompanying illustration the general form of the apparatus which the company has adopted for effecting these changes is shown. The apparatus consists of a longitudinal shaft acting upon a series of switch levers to produce the various connections necessary to place the motors in series or parallel. This controller can be placed at any point beneath the car and operated by a mechanical connection from either end of the vehicle. In this apparatus the mechanical and electrical details have been worked out with the greatest care, and it was permitted to go on the market only after satisfactory tests had been made, proving the efficiency and reliability of the device, on which the company claim to own the controlling patents.

NEW ENGLAND NOTES.

Perry & Demeritt, of Montpelier, Vt., have issued a very interesting illustrated catalogue, showing their well-known "L. P. & D." system of driving dynamos. This system, though comparatively new, has already stood many severe tests, and has been in operation in several electric light stations and isolated plants for some years with marked success. Messrs. Perry & Demeritt claim that with their system they get increased driving power, a large saving in space, and less friction on the bearings, and that it is the cheapest system to set up and the easiest to maintain. The system is extremely simple and substantial, and electrical engineers would do well to investigate its merits while designing electric plants, as it appears to offer them a number of advantages of much importance to them.

The Boston Electric Company, of Boston, report a very large and increasing demand for their celebrated double-armature automatic electric gas lighting burners. These burners are operated by a single impulse of the electric current, which turns on and lights the gas. The armature is so arranged that repeated hammer blows can be given, should the valve become stuck or hard to work an account of friction or poor gas, a property which all other burners in the market, they claim, are deficient in.

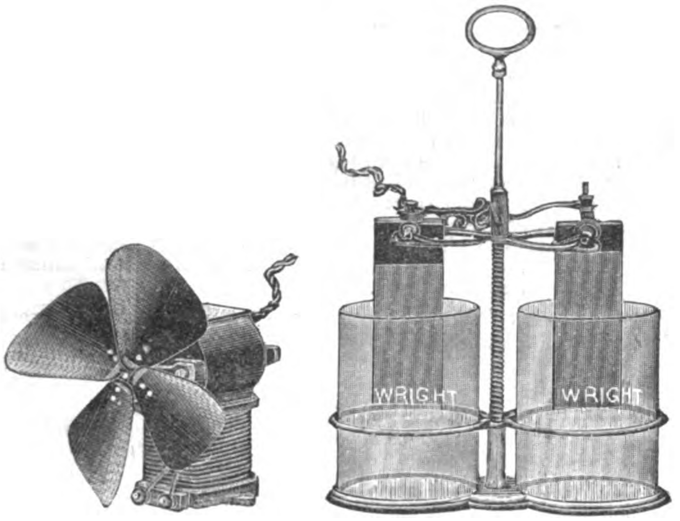
Pettingell-Andrews Company.—At a meeting of the directors of the Pettingell-Andrews Company, Mr. C. H. Price was elected president, in place of Mr. F. E. Pettingell, who has resigned from all active business, owing to his continued ill-health. The other officers of the company remain as before, namely, Mr. D. A. Andrews, Sr., treasurer; Mr. D. A. Andrews, Jr., assistant treasurer, and vice-president; and Mr. C. B. Price, secretary.

Mr. E. R. Tilton has resigned his position with the Pettingell-Andrews Company of Boston, and accepted a position with Mr. C. S. Knowles, of Boston, in the sales department. Mr. Knowles deals in a variety of rubber and other specialties well known to the electrical trade, and Mr. Tilton from his past experience with the trade in New England will form a valuable acquisition to him.

Mr. J. B. Bennett, who for years has been well known as the general manager of the National Telephone Company, has resigned his position with that company, and is now no longer connected with them. Mr. Bennett will keep in close touch with the telephone business, and will announce himself again to his many friends at no very distant date.

"ELECTRIC SAND."

A PRIMARY battery generating current at a cost of $\frac{1}{84}$ cent per horse power hour seems almost sufficiently remarkable to be classed under the head of miracles, yet such an one is claimed by the Wright Universal Electric Co. of 26 Whitehall street, this city. In this battery is used a compound termed "electric sand," and water. The "sand" is a slightly moist, dark-red substance which dissolves readily in the water. No gases are given off from the battery and it is claimed that there is absolutely no local action and that the consumption of zinc is reduced to a minimum.



WRIGHT BATTERY AND MOTOR.

The accompanying illustration shows a two-cell battery driving a Wright fan motor. Each cell contains about five ounces of "sand" and one pint of water. A two-cell storage battery measuring 4¾ x 1¼ x 3⅞ inches is also shown by this company. Measured by a Weston voltmeter this gives a reading of five volts.

The company say they are convinced that they have solved the primary battery problem and are anxious to convince others that they are correct.

PIERCE & MILLER ENGINEERING CO.

THE old firm of Pierce & Thomas having gone out of business, and Mr. F. M. Pierce having purchased the interest of Mr. R. H. Thomas, the Pierce & Miller Engineering Co. will take up the work of the former concern. The new company will continue at the familiar address, 42 Cortlandt street. It will be composed as follows: F. M. Pierce, president; J. D. Miller, vice-president; W. H. Stalnaker, secretary and treasurer; F. Schmerber, chief engineer, and W. B. Hadley, electrical engineer.

These are all well-known and thoroughly experienced men, who between them have an intimate acquaintance with the personnel and practice of mechanical and electrical work. The company will continue as general sales agents of the McIntosh & Seymour Engine Co.; Porter Mfg. Co.'s engines and boilers, T. M. Nagle and the Pennsylvania Boiler Works' engines and boilers, and the Young-Brennan Crusher Co.'s rock and ore crushers. Under its new auspices the company will go more extensively into the business of engineering and contracting for complete steam plants for electric railway, lighting and manufacturing purposes, and will also give special attention to mining equipments.

WESTERN NOTES.

THE RAILWAY EQUIPMENT COMPANY, Chicago, reports for the last week orders for the complete equipment of roads in New Haven, Connecticut; Brooklyn, New York; Baltimore, Maryland; Evansville, Indiana; Chillicothe, Ohio; Pittsburgh, Pennsylvania; Hamilton, Canada; Augusta, Georgia; Kokomo, Indiana, and Put-in-Bay, Ohio. They have also made during the same time large sales for extensions of present roads. The business of this company is constantly increasing. The standard material of their manufacture is known to be reliable, and their facilities for promptly filling orders are unequaled.

MR. ALBERT SECHRIST, electrical engineer, of Denver, Col., expects to take an extensive trip East, this month, which will combine business with pleasure.

SAMUEL F. HODGE & CO., of Detroit, Mich., have adopted the plans of the Berlin Iron Bridge Co., of East Berlin, Conn., for their new foundry, and have placed the contract with the Berlin Company for the construction of the building. It is expected that this will be the most perfect and best-appointed foundry in the Northwest. The general dimensions of the building are 86 ft. in width by 161 ft. in length. On each side there is a wing 23 ft. in width. The centre of the building is controlled by a traveling crane with a travel the full length of the building. The wings of the building are controlled by jib cranes, so that when completed, every inch of the floor surface will be controlled by power, either from the traveling crane or from jib cranes. The construction will be entirely of brick and iron.

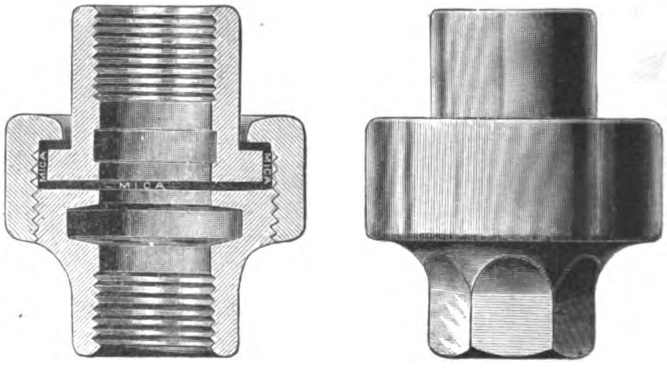
THE MESTON ALTERNATING CURRENT FAN MOTOR is having an immense sale, and although the manufacturers prepared for a very large demand on the strength of their success last year, they are nevertheless already behind on their orders and the demand is daily increasing. The Electric Appliance Company as Western agents report a very large number of sales, and state that their orders come from all over the United States from Maine, Oregon and South to Florida, showing how well they have advertised this specialty. They are carrying a large stock in Chicago and are in the best possible shape to fill orders.

THE SEBASTIAN LATHE CO., of Cincinnati, O., are well and favorably known to all users of machinery and machine tools. They pay special attention to the manufacturing of lathes adapted to electrical work, large and small. It is needless to say that the employment of good appliances of this kind has much to do with the quality of the electrical apparatus turned out, and hence it pays to get tools and mechanical plant from such trustworthy and reputable concerns as that above named.

THE SPERRY ELECTRIC MINING MACHINE CO. are having a very large sale of fuse wire. They were among the first to advocate the use of a tested fuse wire which could be absolutely relied upon to open the circuit upon any excess of current above the predetermined. They have continually made improvements in its composition and manufacture and have accurately determined its action under all conditions. The universal satisfaction given by the fuse wire has made it a prime favorite among users.

MICA INSULATING JOINTS.

THE accompanying illustrations show the "Roberts" insulating joint, manufactured by Vallee Bros. & Co., 17 North Sixth street, Philadelphia. It is small and simple in construction, insulated entirely with mica, and is claimed to be fire, water and acid proof. Ingenious locking devices are used to prevent the turning of the parts upon each other. The illustrations are full size.



THE "ROBERTS" INSULATING JOINT.

COL. WM. M. EDGAR, U. S. Vice-Consul, city of Mexico, is in New York on business, and is the guest of his friend, Mr. Chas. McLaughlin, of the firm of J. H. Bunnell & Co. Under these happy auspices, Col. Edgar has found New York a pleasant place to be in even during the hot weather. As one familiar with Mexico and its history, Col. Edgar makes the admirable suggestion that a fine series of Mexican tableaux could be arranged for El Dorado, the very name having an appropriateness. With the electrical effects in Mr. McLaughlin's hands, we would be glad to see the idea carried out next season. It would make a brilliant hit.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

THE
Electrical Engineer.

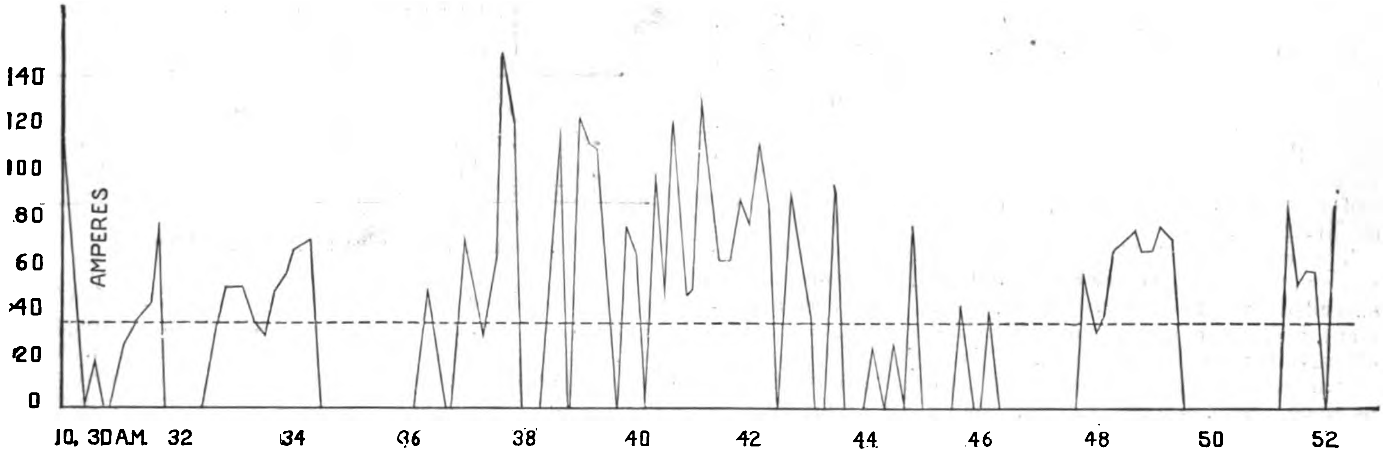
Vol. XIII. JUNE 29, 1892. No. 217.

POINTS ON POWER STATIONS.

BY

Wm Lee Church

BEAR in mind that the engine in an electric railway power station is normally an under-loaded engine,—not an over-loaded engine. That the above statement is not in still larger type is wholly the fault of the printer, and not of the emphasis which the writer desires to give it. Strange to say, a belief precisely the opposite of this seems to be floating vaguely in the minds of most railway men. It would seem somehow, that the abruptness of the load, and the momentary excess which is found every few minutes, had been confused in the mind so as to take the place of the working facts which exist. It is true that an electric railway engine gets frequent and heavy over-loads for an instant, but no more than ought to be comfortably taken care of by the fly-wheel and a proper steam distribution, provided the engine is intelligently adapted for the work. But this over-load has little *direct* bearing on the economy of the engine; in part, because the over-load lasts but a moment, and in still greater part, because a heavy load is, as a general statement, an economical load, within limits depending somewhat upon the type of engine. With reference, however, to the *fuel duty* of the engine, it is not the over-load which is to be principally considered, but the variations of load; and of these variations the minimum load plays by far the greater part in the final economy.



Load Diagram of Electric Railway Power Station.

To put the matter in another light we would say, that the maximum load determines the size of the engine, and the minimum load determines its duty. At this point the investigator is likely to jump to the false conclusion that the *average load for the day* represents the true performance of the engine, upon which he can base his estimate of fuel consumption. This certainly seems reasonable, but nothing can be further from the truth. To make the point clear, we will have recourse to another ampere diagram taken from a small station operating a country line over numerous grades. In this diagram it will be observed that for fully 20 per cent. of the time, there is no load whatever on the engine, other than its own friction and that of the generator. At such times the cars are all for the moment on the down-grade, the circuits open, and the amperemeter at zero. This particular diagram is necessarily confined to a section of but few minutes' run, but the same action was continuous throughout the day. Now the *average* horse power for this run would reduce to the power represented by the dotted line equivalent to 30 h. p.; but this average of 30 h. p. resulted from a continuous fluctuation from 0 h. p. to 125 h. p., and out of this arise some pertinent questions.

Assume that you are about to equip a small power station, and that you are aware of the probable fluctuation of load. Sufficient experience is now available to make this assumption a reasonably safe one. For present purposes we will go to the extreme though not uncommon case, represented by the diagram, and assume that your maximum load will be 125 h. p. It is manifest that you are compelled to select an engine of a rating of certainly not less than 100 h. p. at the determined steam pressure, in order that it may pull over the high spots without sensible diminution of speed. Being limited by this rigid necessity, you next propose to estimate beforehand what your probable coal account will be, since the final statement of the operating account will contain this as a large item. Shall we reckon the fuel duty on the basis of the rating of the engine, say, 100 h. p.? Manifestly not; because the engine gets no chance to work at its rated horse power except at brief and infrequent intervals. Shall we reckon the duty of the engine on the basis of the average of its power throughout the day, as per the dotted lines? Assuredly not; and let us see why. If you jump to conclusions again, you would figure something as follows: "My engine is a 100 h. p. engine, but it will average only 25 h. p. throughout the day. Now if it were running at its rated horse power it would consume, say, 25 lbs. of water per h. p. per hour. (It is assumed to be a compound non-condensing engine of the ordinary type not capable of meeting a fluctuating load.) But since it is operating at an average load of about 25 per cent. of its rating, I will allow that it will use as high as 30 lbs. of water per h. p. per hour; or a total of 13,500 lbs. of water, or, say, 1,350 lbs. of coal, or with banking fires about 1,500 lbs. of coal for an 18-hour run, equal, with $3 coal, to $2.25 per day; and this is what I will figure on in estimating my expense account." And in figuring this way, you would figure exactly wrong, and forever thereafter, you would wonder why you were burning so much coal. Moreover you would gently curse the engine under your breath. Now a matter of fact, *your power averages itself, but your fuel duty does not,* and this is what you never thought of.

Suppose we examine this point. A fuel duty under a continuous rated load, if your engine is a non-compound non-condensing engine of the slow speed variety, would be perhaps 28 lbs. of water, or as low as 25 lbs. with the ordinary compound engine; but even if the engine ran *continuously* at the average load of 25 h. p., its performance would be not better than 45 lbs. which will be fully demonstrated in another paper. Unfortunately, even this condition, bad as it is, almost never exists for more than a moment, but in fact the engine is alternately anywhere from 25 per cent. over-load down to no load at all, that is, no effective load. Under the rated load or thereabouts, you would be getting 25 to 28 lbs.; under a *continuous,* average load, if you had it, you might even get 40 lbs. But under the actual conditions of fluctuating load, out of which your average load is only *computed,* not *created,* you are getting anywhere from 30 to 75 lbs., and varying every moment. If you will now average the fluctuating duties due to the fluctuating loads, instead of averaging the load first, and then assuming a duty based on that, you will find that instead of 30 lbs. you will consume at least 50 lbs. of water per hour for every electrical horse power delivered. This means coal and dollars, and if you never knew it before, you will know it when you come to divide your coal bills by the car mileage. Perhaps I ought not to have taken so extreme a case, though an actual and common one, but all small stations suffer under these conditions, and the larger stations only modify them.

This condition of things, already bad enough, is further aggravated by the power required to drive a more or less extended line of counter-shafting, which power is a constant, and becomes a proportionately greater factor as the effective load becomes lighter. This subject, however, will be treated more fully in another article. The conditions outlined above, as has been said, are found in greatest intensity in the smaller class of stations, and on hilly roads, and to a certain extent become modified as the station becomes larger, the extremes of fluctuation being toned down by overlapping of a greater number of cars. The fluctuation is by no means reduced as much as is popularly supposed, and it is at present a question in the writer's mind whether 1,000 h. p. is not the smallest unit on the single-engine plan, which can with safety be considered in the hope of economical results. It is those small and moderate sized stations which the writer has most heavily on his mind; the big stations get the best attention and treatment, although, I humbly submit, not necessarily the best judgment. The smaller stations are apt to be tinkered up by home talent to save (?) money, or laid out in a general sort of hap-hazard style by some one more interested in the contract than in the engineering results. The fact of the matter is that the small station has the heaviest odds against it in respect to earning capacity any way, as is the general law with all small enterprises, from which it follows that it should, *per contra,* receive the most painstaking engineering in order to off-set this disadvantage and raise its intrinsic operative efficiency to the highest point. In short, give me the small stations and I care not who builds the big ones.

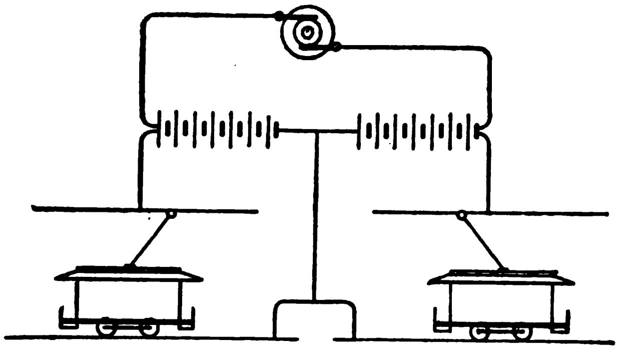
We therefore return to our original proposition and once more repeat that the engine in the power station of an electric railway is essentially an under-loaded engine, and not an over-loaded engine, and must be so treated. Having established this premise, the next and reasonable thing would be to examine the essentials of an engine capable of giving a high duty under light loads; or, more properly speaking, a uniformly high duty under all and wide variations of load. It has been well settled that no ordinary type of engine, compound or otherwise, can accomplish this desired result, even approximately, and since it has fallen in the writer's way to be connected with the development of certain improvements in precisely this direction, it will be the proper object for the next article to make the nature of these improvements somewhat plain.

STORAGE BATTERIES IN RAILWAY WORK.

BY

R. Macrae

The rapid development of electric street railway industries has given rise to the popular impression that in a short time electricity will entirely supersede steam as the motive power on steam railroads. A little study of the plans proposed for moving the trains in the Belt Line Tunnel at Baltimore, as far as they have been made public must, however, lead to the conclusion that present methods of operating electric railroads have to be very considerably modified before the manufacturer of steam locomotives will find his occupation gone. To get rid of smoke in the tunnel the trains are to be drawn through by two electric locomotives, developing about one-half the speed of the ordinary trains. To accomplish this it is proposed to erect a power generating station of 2,500 h. p. capacity. As the largest locomotives now used on the B. & O. R. R. are capable of developing but a little over 500 h. p. at a steam pressure of 150 lbs. it would appear that two steam locomotives of about 250 h. p. each would be sufficient to do the work that will require the erection of a power house of the above capacity when electric motors are employed. Allowing 85 per cent. as the efficiency of dynamos and conductors, 2,500 h. p. will produce a current of 3,245 amperes at a potential of 500 volts. To use such a large current without excessive loss in the conductors it will be necessary to locate the power house about midway between the two ends of the tunnel. This location will be in the neighborhood of the finest residences in Baltimore, and it is possible that the residents of this vicinity might prefer to have the smoke and cinders from two locomotives confined to the tunnel rather than to have the larger amount distributed above ground. With the aid of a few figures we will try to show that by using storage batteries this, and similar work, might be done at a much smaller first cost and in a more satisfactory manner.



STORAGE BATTERIES IN RAILWAY WORK.

The first and most obvious advantage of using storage batteries would be that the generating plant could be reduced from one capable of developing the maximum to one capable of developing only the average current required. With motors having the same relative torque as those now in general use the maximum current required in the case now considered, where only two motor units would be in use, would be at least four times as great as the average current necessary to do the work. This will, no doubt, explain why it is proposed to use a generating plant capable of developing power so much in excess of what at first sight might appear to be really necessary. Taking, then, the average current required at 25 per cent. of the maximum that can be generated by 2,500 h. p., and assuming that the motors would not be in actual motion more than eighteen hours out of twenty-four the average current used would be 3,245 (amps.) $\times .25 \times .75 = 608$ amperes. If we allow 80 per cent. for the efficiency of the battery, the charging current necessary would be 760 amperes at 500 volts This current could be supplied from a generating plant of 542 h. p. By using two sets of batteries connected in series, the charging current might be changed from 760 amperes at 500 volts to 380 amperes at 1,000 volts. The method of connecting up the batteries is shown in the accompanying diagram. The middle of the battery is connected to the earth or rails, and the two ends to the conductors, one over each track. This arrangement would secure all the advantages of a three-wire system without the necessity of using a third wire, at the same time making it impossible to receive a shock of over 500 volts by grounding any part of the system. In the case now considered, the batteries would be placed in recesses in the side of the tunnel, while the higher voltage used would render it practicable to locate the power house at a considerable distance, wherever it might be found most convenient.

The comparative cost of the two systems would be as follows :

2,500 h. p. plant, engines, smoke-stack, power house, etc., at $110 per h. p.	$275,000	500 cells, each weighing 966 pounds and capable of giving a maximum discharge of 1822 amperes, at 25 cts. per pound :	
	180,370	Battery	$120,750
		542 h. p. plant, etc.	59,620
Difference	$94,630		$180,370

This shows a saving in first cost of nearly $100,000 in favor of storage batteries. In estimating the weight of battery necessary, we have taken as a basis the weight and maximum discharge rate of the cells that are at present, and have for many months, been operating successfully one of the storage battery roads in this country.

As the weight of the battery is not so much a consideration in stationary work as the durability of the positive plate, 25 per cent. has been added to the total weight in this estimate to allow the metallic support in the positive plate to be made twice as heavy as that in the portable cells now made. No allowance has been made for the fact that on account of the battery receiving a constant current from the charging circuit the demand upon it would never be more than 75 per cent. of what it would be if used on a car.

As the manufacturer of lead batteries does not require either expensive machinery or skilled labor, the above figures would, we think, allow a fair profit to all concerned. The depreciation of a lead battery is simply the cost of labor in reconstructing the positive plate. The commercial value of the oxide formed by the oxidation of the positive support is somewhat greater than that of the metallic lead necessary to replace it. The oxide can be used over again indefinitely. For stationary work, with ordinary attention, the annual depreciation ought to be less than 10 per cent. The saving in fuel and the diminution in the wear and tear that would result from operating a small generating plant at a constant load, and at its best efficiency, with the advantage of being able at any time to shut down, would more than offset the loss and depreciation in the battery.

In the above estimate we have included the cost of a generating station, but in this case the erection of a power house would not be really necessary. Within a radius of one-half a mile from the tunnel there are four lighting stations with an aggregate generating capacity of over 2,100 h. p. The demand on this power for lighting does not exceed, in the busiest season, an average for the 24 hours of 1,000 h. p., leaving a balance of 1,100 h. p., that could be used for other purposes. After deducting 542 h. p. for moving the train in the tunnel, there would still remain 558 h. p. With batteries located at proper centres of distribution, this power would be sufficient to operate a street railway of 50 cars. Any direct current lighting dynamo could be utilized for generating a 1,000-volt current. Arc light machines might be joined in parallel and incandescent machines in series. If necessary or convenient the batteries might receive current from different stations, payment for the same being made by meter.

By the use of storage batteries located at different points along the route and charged in this way, electric railways could economically encroach more and more on the domain of steam railroads. Natural sources of power, such as waterfalls, would become much more available for the type of railway motors now used, and the dynamos in lighting stations could be kept in almost constant service instead of being allowed, as at present, to sleep all the summer day under canvas covers.

NEW FAN MOTOR OF THE INTERIOR CONDUIT AND INSULATION COMPANY.

Now that the warm weather is upon us, it is a fitting time to make note of the various improvements that have been recently made in fan motors, which add so much to our comfort during the warm summer months. The Interior Conduit and Insulation Company, of New York, are bringing out an entirely new form of fan motor, the invention of Mr. Robert Lundell who is connected with the company.

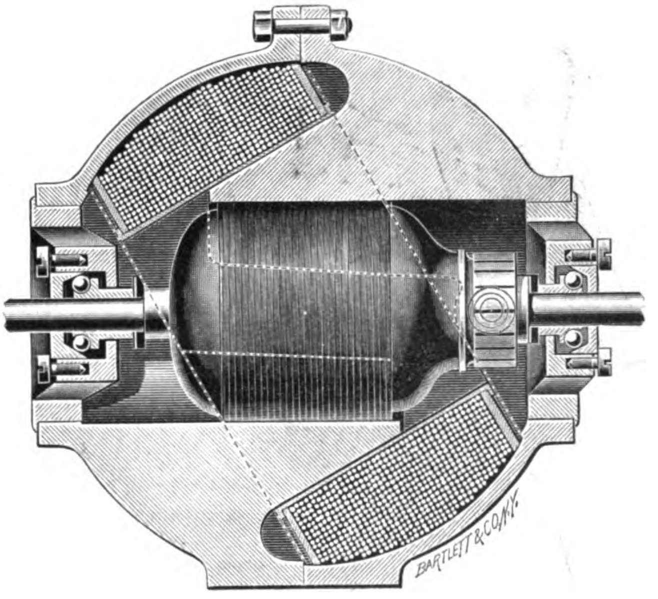


FIG. 1.—LUNDELL IRON-CLAD FAN MOTOR.

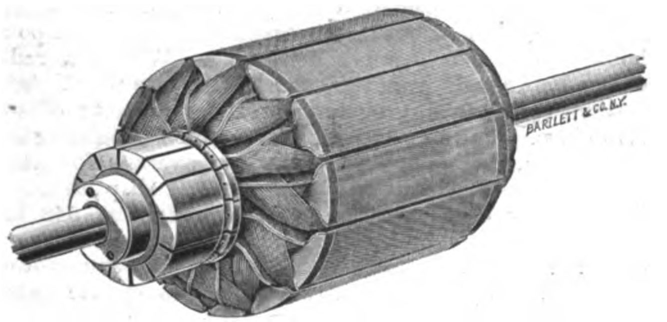
Many attempts have been made to design small dynamos and motors in which there should be practically no magnetic leakage, but in the usual types of motor the leakage frequently amounts to from 40 to 50 per cent. thus requiring an extra heavy magnetic circuit and producing a field magnet of low efficiency. The practical elimination of all magnetic leakage constitutes the chief factor of efficiency in the new Lundell motor, although it is not the only one.



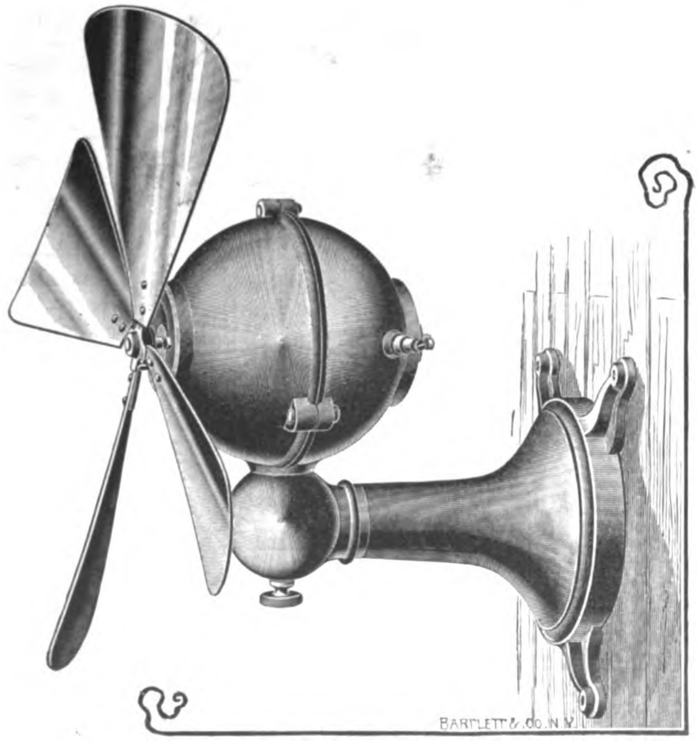
BARTLETT & CO. N.Y.

Fig. 2.—Armature of Lundell Fan Motor.

This great desideratum is attained in the manner shown in Fig. 1. As will be seen the armature and pole-pieces are surrounded by a single magnetizing coil, which, in turn, is itself totally surrounded by the keeper or yoke, thus leaving no chance for stray magnetism. It is a true iron-clad field magnet, having at the same time the shortest possible magnetic circuit. The keeper would form a perfect sphere were it not for the slight projections constituting the bearings.

The motor assumes wonderfully small dimensions for any given capacity, due to the fact that every cubic inch of space inside the spherical keeper is effectively utilized. It is also very light on account of a short magnetic circuit having the smallest possible cross-section, with comparatively few turns of wire in the magnetizing coil.

The type of armature adopted, as shown in Fig. 2, is a modern Pacinotti drum, proportioned with a view to maximum efficiency. In the design of the motor particular attention has been paid to the shape of the pole-pieces in relation to the reaction between armature and field magnet.



BARTLETT & CO. N.Y.

Fig. 4.—Bracket Fan Motor.

Thus the motor has been rendered sparkless, and the point of commutation remains fixed between the limits of load and at reversal of rotation. The need for a special rocker-arm for supporting and adjusting the brushes is consequently obviated. The brushes themselves are small carbon pencils, fitted in bayonet-jointed holders, and held upon the commutator by a small spiral spring.

The new motors are furnished in five different styles, the engraving Fig. 3 showing the regular desk fan with wire screen. Fig. 4 illustrates the bracket fan motor and demonstrates the ready adaptability of the motor to be placed in almost any position. By means of a neat suspension chain the motor can also be readily hung from the ceiling and with equal facility set to drive a vertical ceiling fan.

The $\frac{1}{12}$ h. p. motors are all fitted with ball bearings which require no oil, a most valuable consideration. They run at a maximum speed of 1,800 revolutions per minute, a minimum speed of 900 and a mean speed of 1,150 at 110 volts E. M. F.; while the $\frac{1}{8}$ h. p. motors have a maximum speed of 1,800 revolutions, a minimum speed of 900 and a mean speed of 1,000 revolutions per minute.

ELECTRIC CRANES FOR THE WORLD'S FAIR.

Visitors to Machinery Hall will be enabled to pass from one end of the building to the other at an elevation, and thus gain a bird's-eye view of the vast area of exhibits, and to see many of the larger exhibits to much greater advantage than will be possible from the floor. To accomplish this three mammoth electric traveling cranes will be constructed, each with a lifting and carrying capacity of 40,000 pounds. Contracts for their construction have been let to the Yale & Towne Manufacturing Company of Stamford, Conn., the Morgan Engineering Company of Alliance, Ohio, and the Edge Moor Bridge Works of Wilmington, Del.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* The Electrical Engineer. *Communications for the attention of the editors should be addressed,* Editor of The Electrical Engineer, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

Vol. XIII. NEW YORK, JUNE 29, 1892. No. 217

It is doubtful if any great truth has ever been lost; though some may have apparently lain dormant for a time, yet they have continually produced results.—Joseph Henry.

CONFLICTING ASPECTS OF LAMP LITIGATION.

THE decision of Judge Acheson, in the suit of the United States Electric Lighting Company against the Edison Lamp Company for alleged infringement of Weston's patent for hydrocarbon treatment of carbon burners for incandescent lamps, an abstract of which we publish in another column, may or may not mark an important epoch in the history of incandescent lamp litigation, but it will certainly have the effect of raising some decidedly interesting and important legal questions. Judge Acheson holds that the public exhibition by Sawyer and Man of a "large number of incandescent lamps" containing treated or flashed carbons, between March, 1878, and May, 1879, was "a practical and public use." This, it will be noted, was some time prior to any attempt by Edison to make use of carbon. Sawyer and Man took out two United States patents, and at least one British patent, covering their invention of hydrocarbon treatment. The British patent, known as the "Cheesbrough," of November 28, 1878, was fully sustained by the highest courts of that country, after protracted litigation, its principal claim being for the "method of preparing the illuminating portion of an electric lamp, consisting of electrically heating the same while it is surrounded by a carbon gas or liquid." The first domestic patent (No. 211,262), dated January 7, 1879, was similar to the British patent, except that the process claimed was, for some unexplained reason, limited to immersion in hydrocarbon "liquid." After the issue of this patent, the United States Electric Lighting Company filed a conflicting application, claiming priority of invention in behalf of Edward Weston, making substantially the same claim as that of the above-mentioned British patent, and ultimately succeeded in securing the patent which has now been pronounced invalid by Judge Acheson. The present adjudication is, therefore, in effect, an affirmation of the validity of the Sawyer and Man patent. Moreover, on November 29, 1878, Sawyer and Man obtained a second patent covering an electric burner of carbon "consolidated and purified by electrical treatment in combination with a carbonaceous substance," which, of course, embraces treatment by gaseous as well as liquid hydrocarbons. But it will be noted that both these patents were issued, and one of them was applied for, subsequent to the date of the British patent for the same invention, which circumstance still further complicates the legal situation. Both of these Sawyer and Man patents, as well as the discredited Weston patent, are now controlled by the Westinghouse Company, a fact which is the more interesting to lamp manufacturers, inasmuch as nearly all the incandescent lamps now made contain carbons which have been treated by the hydrocarbon process. Another point of interest in connection with Judge Acheson's decision is, that the finding is directly contrary to that of the late Judge Bradley, in the McKeesport fibrous-carbon case, who, upon precisely the same evidences of fact, held that the work of Sawyer and Man was not a "practical and public use," and hence did not anticipate Edison's subsequent discoveries. In short, it looks very much as if the prospect of a final settlement of the legal status of the incandescent lamp, in view of this decision, was farther off than ever.

GROUNDING THE NEUTRAL.

Insurance bodies, especially those in New York, have of late made considerable ado over the practice pursued by the local Edison Company in this city in grounding the neutral on their three-wire system. While those opposed to this practice point out the dangers arising from a permanent ground on any electric system, the advocates of the method of grounding contend that by the practice pursued the entire system is relieved of one-half the strain on the insulation, and that hence the liability to leakage is reduced just to that extent. It has been generally supposed that the practice of grounding the neutral was only practiced in this country and in a few isolated cases, but that it is practiced abroad, by reputable firms, will be somewhat of a surprise to the opponents of this method. In a recent number of the *Elektrotechnische Zeitschrift* we note that the well-known firm of Schuckert & Co., of Nuremberg, employed the grounded neutral in their installation at the Frankfort Exhibition, and that the station put in by them at Altona near Hamburg is now operated on a like plan. They also draw attention to the fact that the uninsulated conductors laid in the ground in the immediate neighborhood of telephone and telegraph offices gave rise to no complaint. The same practice appears to be in vogue in Athens, but the only difficulty there encountered is due to the fact that the lead armor with which the conductors were covered was employed as the return neutral in contact with the earth; hence electrolytic action set in which destroyed the lead covering. Where such a covering is not employed, however, it is apparent that the difficulties in this respect would not be encountered. We have deemed it well to call attention to foreign practice in this respect, in order to show that electrical engineers abroad have also recognized that the grounded neutral possessses advantages, and that if properly carried out it is not as dangerous a plan as some would have us believe it is.

STORAGE BATTERIES IN RAILWAY WORK.

While the storage battery as applied to electric railway work has heretofore been considered almost exclusively from the standpoint of its application directly to the cars to be driven, but little attention has apparently been bestowed upon the method of its utilization in the power station itself. It goes without saying that in electric railway work, for the most part, large fluctuations in power will be encountered, and if by any means the economy of operation can be increased, all means to that end ought to be applied. In considering the application of electric locomotives to the propulsion of trains through the Baltimore tunnel, Mr. Macrae, in this issue, argues that by the use of storage batteries better results would be obtained than by the application of the current direct. Mr. Macrae's figures, it is true, are only approximate and based on the assumption that the difference between the mean and a maximum load would be as great, in the case considered, as in the ordinary electric road operating only two cars. Until the detailed amount of traffic passing through the tunnel is known, it would be hardly practicable to form an intelligent judgment as to which plan would be the better, but the suggestion of Mr. Macrae appears to be worthy of respectful study.

UNDERGROUND ELECTRIC RAILWAYS.

The commissioners appointed by the General Term of the Supreme Court to decide whether the railroads proposed by the Rapid Transit Commissioners may be constructed according to the plans and specifications of those commissioners, such decision to be in lieu of the consents of the abutting property-owners, have decided broadly in favor of the scheme laid out. The plan recommended is practically an underground road from the Battery to Fifty-ninth street and to One Hundred and Twenty-first street, and thence to city limits by viaduct or underground structure. There is also included an east-side line up to Forty-fourth street, from Fourteenth, and a loop down town around City Hall Park. In regard to the motive power, the commissioners declare that electricity can be used, and that the conclusion has been arrived at after consultation with experts. The commissioners further express their belief that capital will be readily forthcoming for the enterprise. Argument is to be heard on June 29 as to the acceptance of this report.

It is significant that while an American body has thus been deciding again in favor of underground electric traction, an English body of even more importance and influence has placed itself on record in similar terms. A joint committee of the two British Houses of Parliament, having under consideration the numerous plans for extending the underground electric railway service of London, in which it is proposed to expend several millions of dollars, has expressed its opinion in favor of the underground system, and also reports that the evidence as to the adequacy and reliability of electricity is convincing. Even should New York still be denied the rapid transit facilities it so badly needs, London bids fair to enjoy soon an underground electric system of proportions fully equal to those of the old steam tunnel system, now admitted to be behind the march of improvement and the demands of the day. But there is no good reason why New York should lag behind in any respect of modern convenience and advantage. In fact, of the two cities, New York has probably the inferior facilities at the present time, owing to the restriction of travel in the busy hours to a single direction; so that even a small measure of relief, enough to keep pace with the mere normal rate of increase, would be welcome.

THE GROWTH OF THE THOMSON-HOUSTON COMCOMPANY.

We publish in this issue from the pen of Mr. A. C. Shaw an article of unusual interest, descriptive of the rise and growth of the Thomson-Houston Co., and of its present plant and processes. This company has gained its prominence through one of the rarest combinations of inventive genius, financial skill and executive ability that the world has ever seen, and it was fitting, that as it now merges into an even larger organization some note should be made in this manner, of its evolution. If success have any lessons for us, there must be much of instruction and suggestion in such a brilliant record as this. To us, one of the most striking features of the story is that the company made its humble beginnings at a time when it seemed as though the mighty competitors already in possession of the ground had pre-empted every opportunity of growth and prosperity. What encouragement lies in this fact for brains and capital embarking to-day in electrical enterprises! After all, in electricity, the greater does not lie behind, but beyond.

An "I Am Sir Oracle" on Electric Railways.

One of the most persistent opponents of the trolley system for Brooklyn and New York has been Mr. David M. Stone, the venerable editor of the *Journal of Commerce*. That he knows what he is talking about may be inferred from the subjoined passage, which appears in one of his articles under date of June 20: "It will never be safe to ride in a trolley car while the present system is used. The passengers cannot avoid the influence by induction of the electric current. *Palsy will be common* among the throng of those who will use these means of conveyance, and life's currents will be checked by the unseen agent so little understood but so recklessly employed." Such a case of ignorance as this is certainly hopeless. Evidently, the unseen agent is very "little understood" by some who would set themselves up as Sir Oracles. But for Mr. Stone's long years of public service, his language "so recklessly employed" would warrant about as severe a rebuke as could be given it.

"T.-H."; or Among the Dynamo Builders of Lynn.

BY

A. C. Shaw.

I.

UNTIL within the last ten years the town of Lynn, Mass., was but little known to any one outside of the shoe trade, in which business it had undoubtedly earned a wide reputation. It was little thought at that time that it would become the home of so large an electrical industry as that represented by the Thomson-Houston Electric Company. Now, it would be safe to say, not only is there no one who is interested in the smallest way in electrical pursuits who has not heard of Lynn, but there are few who have ever had the opportunity who have not visited this town which contains, probably, the largest electrical industry in the world. It will, therefore, be a matter of universal interest to present to our readers a description of the factories of the Thomson-Houston Company, with a few brief notes of their methods of manufacture and some description of the various goods which are daily being turned out for shipment to all parts of the world in this busy town on the coast of Massachusetts.

II.

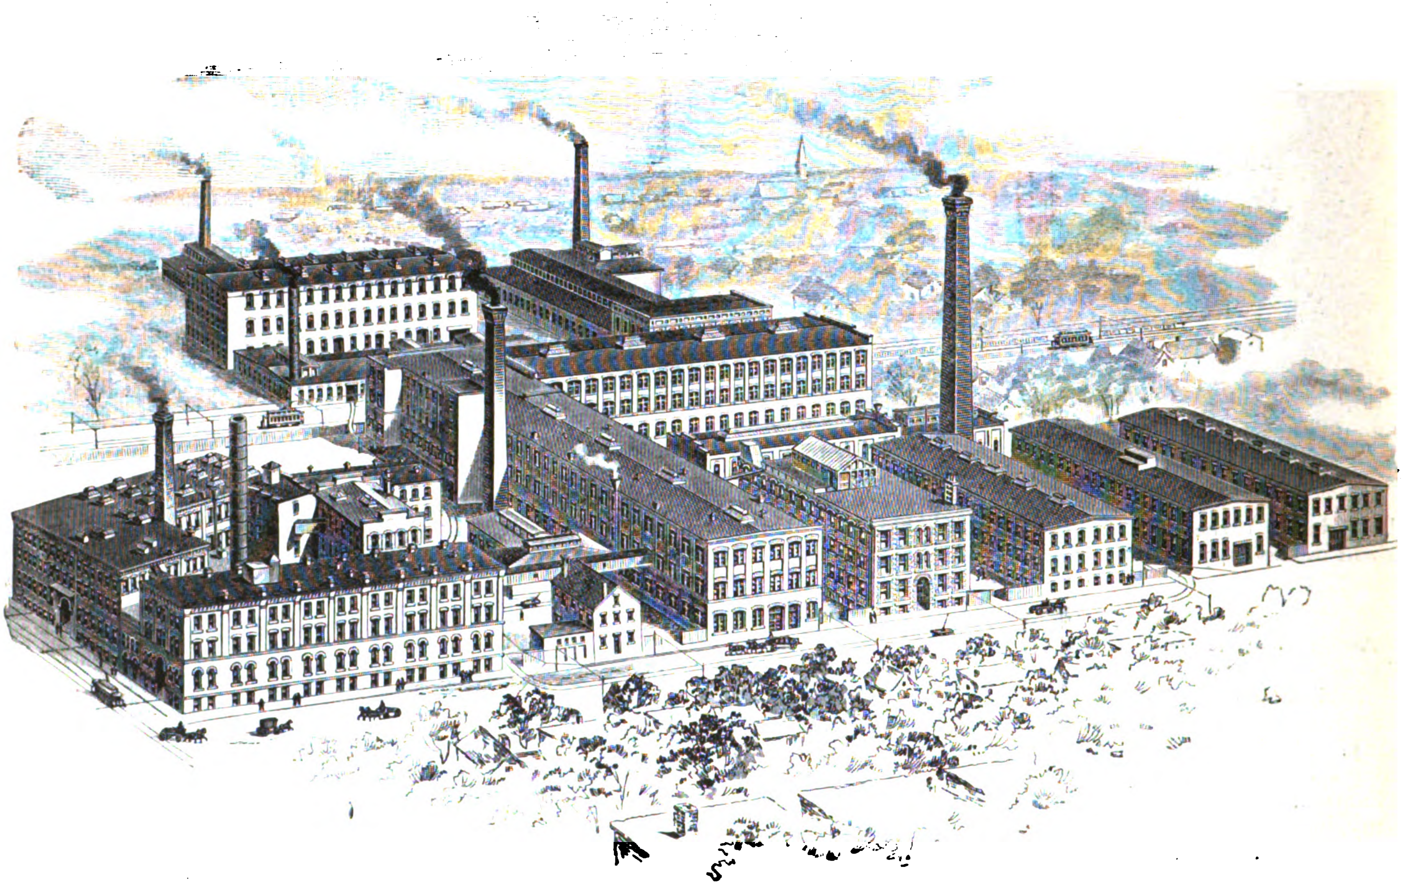
Among the manufacturers of the larger and heavier classes of electrical apparatus in this country, there is probably no company whose history contains so unbroken a record of successes as that of the Thomson-Houston Company. Much of this is naturally due to the inventive genius of the founder of the industry, Professor Elihu Thomson, but the wonderful business success of the company, in its growth from a small manufacturing concern in New Britain, Conn., with a paid up capital of only $87,500 to the gigantic organization of to-day, with its capital of $18,400,000, is undoubtedly the result of the brilliant financial management of Mr. C. A. Coffin, the general manager of the company, and the living mainspring of the whole concern. The Thomson-Houston Company was originally formed in 1880 in New Britain, under the name of the American Electric Company, to manufacture arc-light dynamos from the designs of Prof. Elihu Thomson and Prof. E. J. Houston, who had previously successfully built an eight-light dynamo with automatic regulator in a small shop in Philadelphia. The newly organized company secured the old Stanley works for their factory, and struggled along for the first two years very slowly, but overcoming many difficulties, and laying a solid foundation of valuable experience and good patents. In the early part of 1882 the majority of the stock fell into the hands of the president of the Brush Company, who, however, in the fall of the same year, having made no endeavor to push the business, allowed it to lapse into the hands of certain Lynn capitalists. These gentlemen, headed by Mr. H. A. Pevear, S. A. Barton and C. A. Coffin, immediately reorganized the business on an active basis, and changed the name of the company to the Thomson-Houston Electric Company, obtaining a charter previously granted under the laws of Connecticut, with a capital of $87,500. The business was still carried on at New Britain, but preparations were early made to transfer the factory to Lynn, and a building having been erected in that city on Western avenue and Federal street, the removal of the machinery took place in the fall of 1883, and we present a picture on this page of the factory as it appeared in 1884, and which is now used as factory A, shown in the plan. Since that time the business has gone on steadily increasing, and new branches have been constantly added, including the direct incandescent, alternating incandescent, motor and railway work, and lastly the mining department. As the business increased the factory facilities were naturally increased, until from the original floor space of 26,962 square feet, they now occupy 342,000 square feet, or about eight acres. In the same way the number of operatives in January, 1883, was only 45, while in January, 1892, they were 3,492, and at the present time there are more than 4,000. On July 22, 1880, the capital stock was increased to $125,000; on May 24, 1887, it was increased to $500,000; and on March 8, 1888 it was increased to $1,000,000. It ultimately reached $18,400,000, and, at that stage, merged with the Edison General Electric Co., with which it will now constitute the General Electric Co.

THE OLD THOMSON-HOUSTON FACTORY AT LYNN, 1884.

III.

To assist our readers we show on page 658 a plan of the factories as they stand at the present time, each one of which is known by a letter of the alphabet and so designated on the plan.

In describing the numerous departments of the factories, it is natural to commence, with the large machine-shop designated first L, in the plan, where all the large castings are received, and undergo their first treatment. Up to the present the Thomson-Houston Company have had no foundry of their own, but have had all their iron castings made outside, though arrangements are now being perfected whereby they will run their own foundry, and thus be enabled to produce a finished machine from the rough pig iron, to the completed dynamo ready to be set up in its appointed place. This machine-shop shown in our engraving on page 649 is a large well-lighted room, measuring 75 feet by 187 feet, and occupies two stories of factory L, with a gallery at either side, used for winding armatures. Heavy machine tools are arranged along either side, and the fitting together of the parts is done in the middle of the shop. The shafting for this shop is all run by railway motors, of which there are five situated in convenient places. The machine, tools consist of heavy planing machines, lathes, drills, special machines for boring the inside of the pole-pieces of the various classes of dynamo, and some special machinery for boring the large 670 h. p. M. P. 500-volt railway generators. Here may be seen all kinds of dynamos and generators in their initial state, and it is interesting to see the easy way in which the parts of these large electrical monsters are prepared for being ultimately fitted together, some having their flanges planed, some having holes bored for fitting together, and others in a more finished state having been bolted together, having their pole-pieces bored out, and their rough edges dressed down. Overhead, running on rails on a level with the gallery, is a huge 30-ton traveling crane, manufactured by the Morgan Engineering Company of Alliance, O., and operated by three T. H. motors, so that it has three simultaneous movements, being able to move along the length of the shop, raise or lower its load, and at the same time move it across the breadth of the shop. By means of this crane every inch of floor space is made available and the utmost economy in handling the heavy castings is attained. In addition to the crane, there is also a track leading through the middle of the shop, on which castings can be transported from one part of the factory to any other on motor trucks.



BIRD'S EYE VIEW OF THE THOMSON-HOUSTON ELECTRIC CO.'S FACTORIES, LYNN, MASS.

Passing into the adjoining factory C on the same floor, we reach another huge machine-shop, which is devoted chiefly to the machining of the railway motors, of which a multitude can be distinctly seen in our illustration on page 650 stacked up in rows, either awaiting their turn to be planed and bored, or finished ready to be moved on to the next process. In this room there is a huge array of planing machines, shown on page 651, each one capable of planing four W. P. motors at one time, and at the further end is situated a forest of drilling machines, which bore the necessary holes for bolts and other purposes. In this shop also the fields of the W. P. motor are bored, and the bearings are all fitted with brasses, the present capacity of the shop being 150 W. P. motors per week. In one corner of this shop may also be seen a number of men busy building up the armature cores from the soft laminated iron, and some half dozen very ingenious machines working hard cleaning out the slots in the iron-clad armature cores, so as to leave them perfectly smooth for the winders.

IV.

Passing up stairs in this building we come to second C, in which there are a number of different operations going on. The end near factory L is devoted to assembling the railway motors, putting on the field spools, inserting the armature, and then submitting them to a crucial working test, by gearing them to one another in such a way that one motor is run as a receiver, while the other is made to work as a generator. In another part of this room also the assembling and testing of the smaller generators take place, it being devoted to alternating dynamos, railway generators and direct current incandescent dynamos of the motor type up to about 100 h. p. The spool winding for the motors is also done on this floor, and a large number of men are kept in constant work on this operation. The further end of this room is devoted entirely to the testing of transformers of all sizes. These are arranged on shelves around a small apartment, carefully partitioned off from the rest of the room, and have to stand a test of several hours under full load. Each converter is also tested up to 5,000 volts before being filled with oil and sealed up, by means of a transformer having a range up to 10,000 volts. Here also the accommodating attendant will be glad to demagnetize the visitor's watch, should it have become magnetized, by inserting it in a coil of wire, in which the alternating current is flowing, attaching it to a string, revolving it rapidly, and gradually withdrawing it from the influence of the magnetic circuit.

Machine Shop in Factory "L" for Handling Heavy Work.

Passing up stairs again into the third floor of factory C, we come first to the manufacture of transformers. Here the laminated iron cores are pressed together by the machine shown in the accompanying cut on page 652, and the spools of the primary and secondary circuits, which are also wound on this floor, inserted in place, after being carefully insulated. Further along may be seen the manufacture of switches and resistance boxes, with all their accompanying parts of slate bases, insulated handles, German silver resistance coils, and other details. The remaining third of this floor is entirely devoted to the manufacture of commutators, and we present a view of this interesting process in the accompanying engraving, page 652. Here may be seen commutators in all stages of manufacture, one man trueing up the segments, before putting them together, another inserting them in two iron bands with innumerable screws for compressing them into the desired size, and insulating them with mica, while others are busily engaged turning them down, and fitting on collars or end plates for holding them in their true position. Here also may be seen commutators of all sizes, from a small one of three inches in diameter to the largest commutator for the 670 h. p. generators measuring 25 inches diameter, composed of 180 segments and weighing, when completed 1,950 pounds.

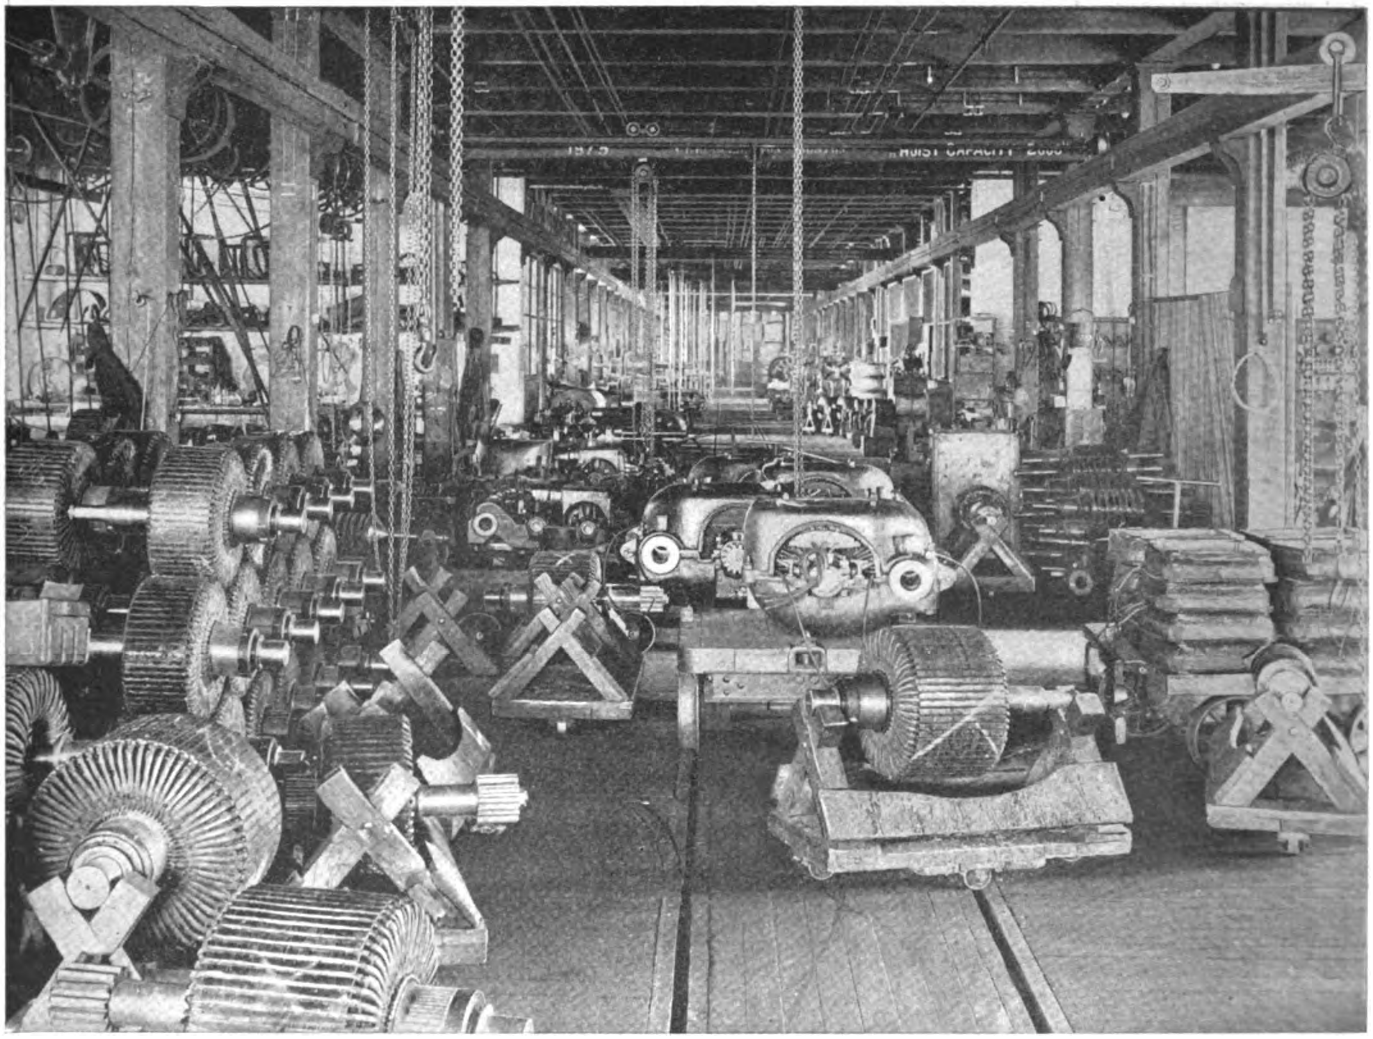
V.

Leaving factory C and returning to factory L on the second floor, or rather the galleries of the large machine-shop, already mentioned, we arrive at the armature winding department, which appears at first sight to be the busiest scene in the whole factory.

Standing at the door and looking down the length of one of these galleries, are seen a veritable army of men all engaged in winding railway motor armatures. Over 400 men are employed in these two galleries all busily engaged in winding the armatures which are arranged on each gallery in four long rows, with two men at each armature. The one gallery is entirely devoted to railway motor armatures, while the other contains a number of armatures for various purposes and of various design, W. P. railway, S. R. G. railway, alternating and drum type for incandescent work.

At the end of this hall there is a small communicating gallery from which our view of the machine-shop is taken, and from which can be seen at one time over 400 men at work.

Passing again up stairs on to the third floor we reach another machine-shop, shown on page 653, filled with a lighter class of tools than those in the other machine-shops. Here all the pinions for the railway gears are made, being cut out by gear cutting machines from solid steel forgings. The dust-proof oil cases for enclosing the gears are also made on this floor, together with the self-oiling boxes, for the bearings, which form a particular feature of all Thomson-Houston machines. Bearings, light shafting, key seating and a host of similar work is also in full progress on this floor, while the small motors up to 15 h. p. are here assembled, afterwards being taken to second C for testing before shipment.



Machine Shop for Finishing Railway Motors, Factory "C."

VI.

Having thus completed our visit to factories C and L, we now pass on to factory A, and find ourselves in the region of the well known familiar arc light machines. On the second floor as represented on page 652 a number of men are employed in winding the coils for the spherical armatures, so well known that they need no description. In another part of this room, the heavy spools for the field magnets of the heavy railway generators are being wound, while in a corner by themselves the small magnets for arc lamps are being wound by the hundred.

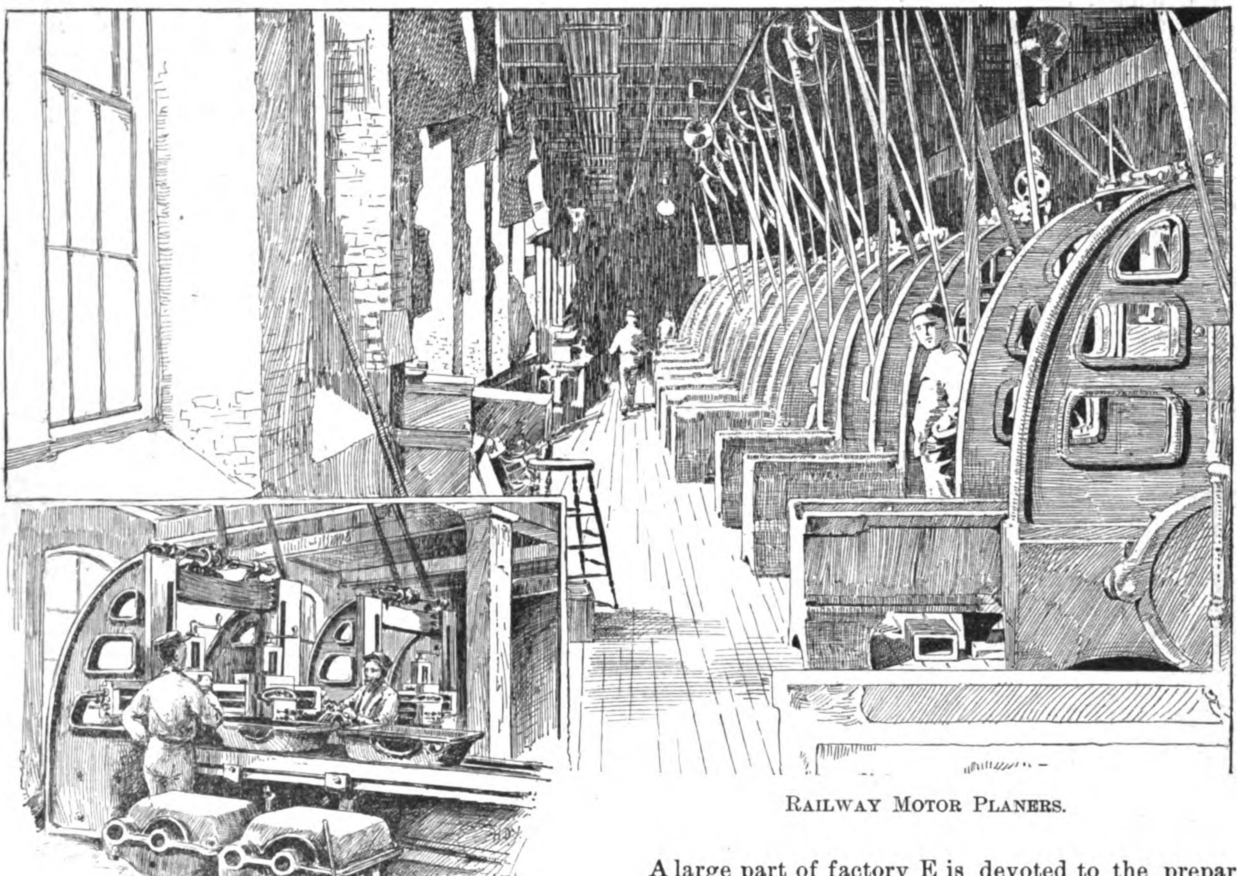
The first floor of this building is devoted to the assembling of arc lamps, and in boxes and other receptacles are seen thousands of parts of the well-known type of Thomson-Rice arc lamp. Accommodation is also here provided for a large stock-room, while another part of the floor is devoted to the manufacture of the innumerable small special tools used in the manufacture of the various electrical apparatus in the different shops.

The third floor of A is devoted entirely to the manufacture of incandescent lamps of various candle powers and voltages. In another part of the factory a number of boys are engaged in unpacking the glass as it comes from the glass works, cleaning it out and sorting it into various portable rack trays by which it is conveyed to the men who afterwards fashion it into the necesary shape for receiving the filament. The glass blowers, working at benches, upon which the necessary blow pipes are mounted as shown in our picture on page 654, first take the glass bulb, open up the round end and carefully seal in the exhausting stem. At the other end of the room are arranged several rows of girls all busily engaged in sealing in the already prepared filament after having cut the globe to the proper length, and preparing the lamp for the process of exhaustion which is done in another part of the factory. This floor makes a very pretty and interesting scene, and it is extremely fascinating to watch the expert fingers of the girls as they deftly fit the two parts of the lamp together, apply the flame, expertly spin the lamp around and in a few minutes lay it aside on the waiting rack to be carefully carried away to the exhausting-room. Small vari-colored seals are also pasted on to the lamps, each seal denoting a different voltage or candle power, and preventing any chance of mistake after completion.

VII.

Passing into factory B, on the second floor we reach a large room also devoted to the manufacture of incandescent lamps. At the north end of this room is a large stockroom from which the daily shipments are made. Next to this are the large racks on which the finished lamps are tested, the lamps all being screwed on to the standard sockets by boys who work on piece-work, and who have got so expert by experience that they can insert five lamps in about the time it would take any ordinary person to insert one. In the other half of the room about 30 girls are employed fitting the lamps with collars, as shown in the illustration on page 652. These collars are filled with plaster of paris, and the connecting wires are led through and soldered to the collar. The lamps are then washed and passed into the photometer-room, which stands in a corner by itself and which is entirely secluded from the other parts of the room. The photometric system employed here is very complete, and the process is extremely interesting. The lamps are mounted on a revolving circular frame, which contains five lamps at one time, and alongside is the standard lamp from which by comparison the measurements are taken. As soon as the lamps are connected they are illuminated by a current the voltage of which can be changed by rheostats under the control of the girl who compares the shadows on the photometer with the shadow of the standard lamp. The work is done on piece-work and is conducted in a marvelously expeditious manner. One girl attends to the revolving frame, putting in new lamps, and taking care of the lamps measured and marked. A second girl reads the voltmeter at the moment the shadows are announced to be alike. A third girl marks the lamp with the exact voltage, while a fourth girl measures the shadows and handles the rheostats. As the measuring by shadows is apt to be rather trying on the eyes, the order of things is reversed after measuring each tray of lamps.

The pump-room for exhausting the lamps is situated on the floor above, and contains several hundred of both Geissler and Sprengel pumps, having a united capacity for exhausting 5,000 lamps a day. The Packard vacuum pumps for creating the vacuum necessary to operate the mercury pumps are situated in the basement of the building, and are also used as usual for the preliminary exhaustion. There is used in this pumping-room about 15,000 pounds of mercury to operate the various mercurial pumps, which gives some idea of the magnitude of the work here carried on in the manufacture of incandescent lamps.



RAILWAY MOTOR PLANERS.

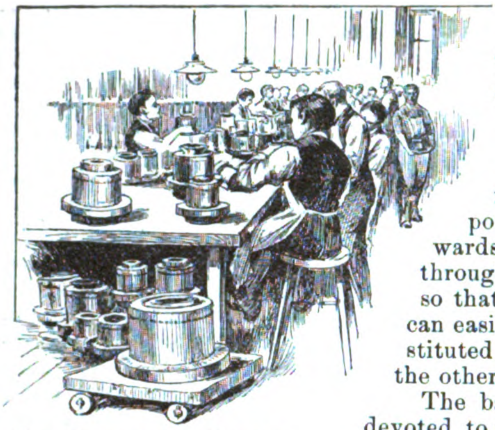
PLANING RAILWAY MOTOR CASINGS.

A large part of factory E is devoted to the preparation of the carbon filament and many of the methods are original and have been carefully worked out. Some 65 or 70 girls and boys are employed on this work.

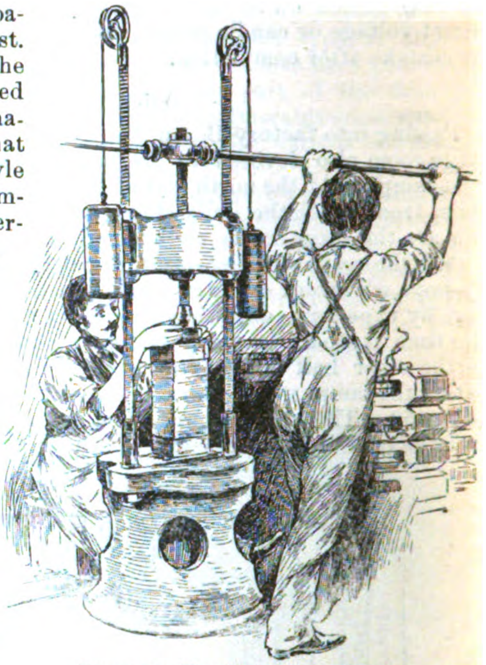
VIII.

Passing on in factory B, on the second floor we reach the department shown on page 652, devoted to the testing of arc lamps, a sight which at first is rather trying to the eyes, as the racks from which the lamps are suspended can accommodate about 170 lamps, which produce an amount of light not altogether comfortable. Further along there is situated a number of light machine tools for the manufacture of the small parts of the arc lamps, while arc lamp switchboards, fuse boxes, magnetic cut-outs and lightning arresters are also made on this floor.

The basement of factory B, is largely devoted to the testing of incandescent dynamos of the spherical armature type. A Corliss engine is provided for this purpose fitted up with every convenience for telling the horse power consumed, while there are all kinds of instruments for ascer-



The Commutator Department.

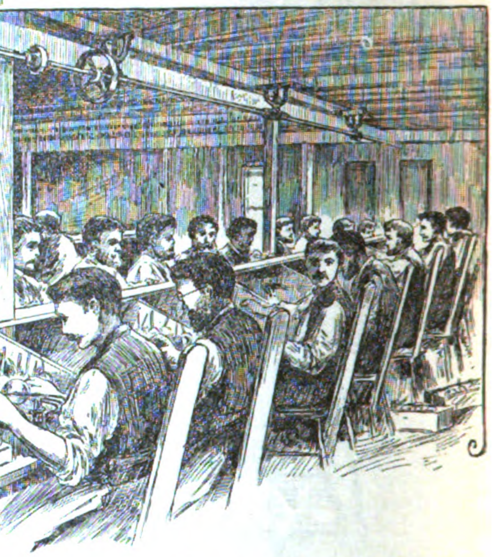


Pressing Transformer Cores.

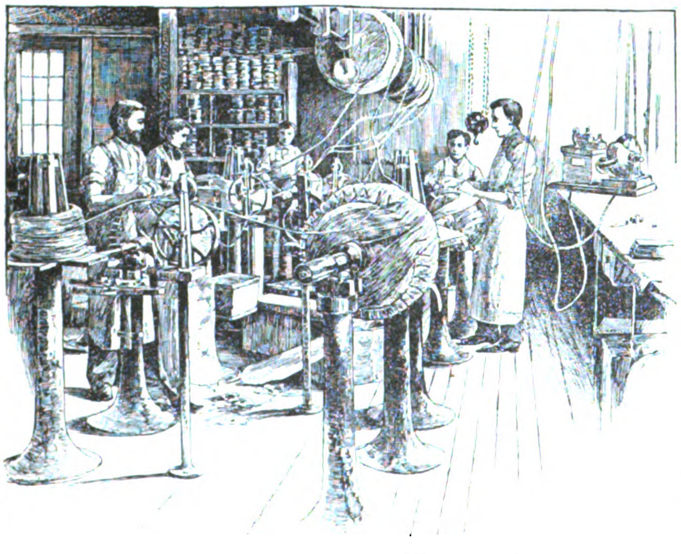
taining the exact voltage and capacity of the dynamos under test. The new type of armature for the arc light dynamos is also assembled on this floor. This form of armature does away with the somewhat complicated winding in the old style machine, the winding being composed of 30 small coils which are afterwards slipped on to the armature, through a specially prepared opening, so that any coil, should it burn out, can easily be removed and another substituted without affecting in any way the other coils.

The basement of factory A is chiefly devoted to the manufacture and testing of arc light dynamos as well as the manufacture of the frames for the spherical type of dynamos, and the building up of armature cores. All the spherical dynamos are assembled in this shop, while the adjoining basement of factory E is devoted to the building and turning of armature cores.

Leaving factory A, we next arrive at factory I, which has two floors entirely devoted to carpenter work, in which the hanger-boards for the arc lamps, switch and fuse boxes, and all the woodwork necessary on electrical apparatus is made. This shop is well supplied with circular saws, band-saws, planing machines, milling machines and all the necessary machinery for this purpose. Here also the patterns for the various castings are made, from which they are sent to foundries in the vicinity.



In the Incandescent Lamp Department.

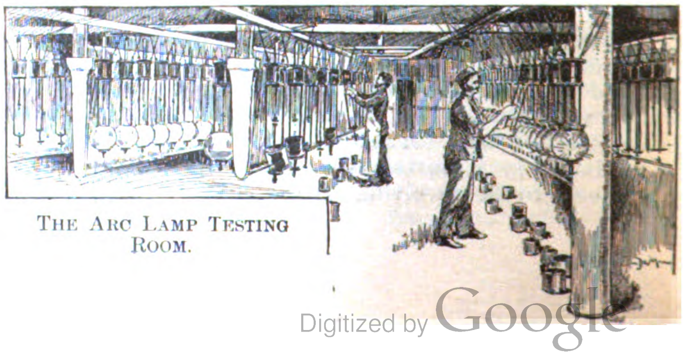


A Corner in the Arc Armature Winding Department.

IX

Factory J presents a very busy scene and is chiefly occupied by girls who are engaged in splitting and gauging mica used in the insulating of the commutators. The mica is received in barrels and is first sorted out by men who pass it on to the girls to be split up. A large number of girls are employed in this work and there are consumed in this room a large number of barrels a week. The mica is afterwards stamped out into the desired shape, and then tied in bundles and distributed to the various departments where it is used. Mica scrap is also used in the insulation of the large armatures, being pasted onto strong canvas and then cut up into long strips. One end of this room is devoted to tinsmith work, where all the guards for arc lamps are manufactured, and all other tin and copper work used with Thomson-Houston apparatus.

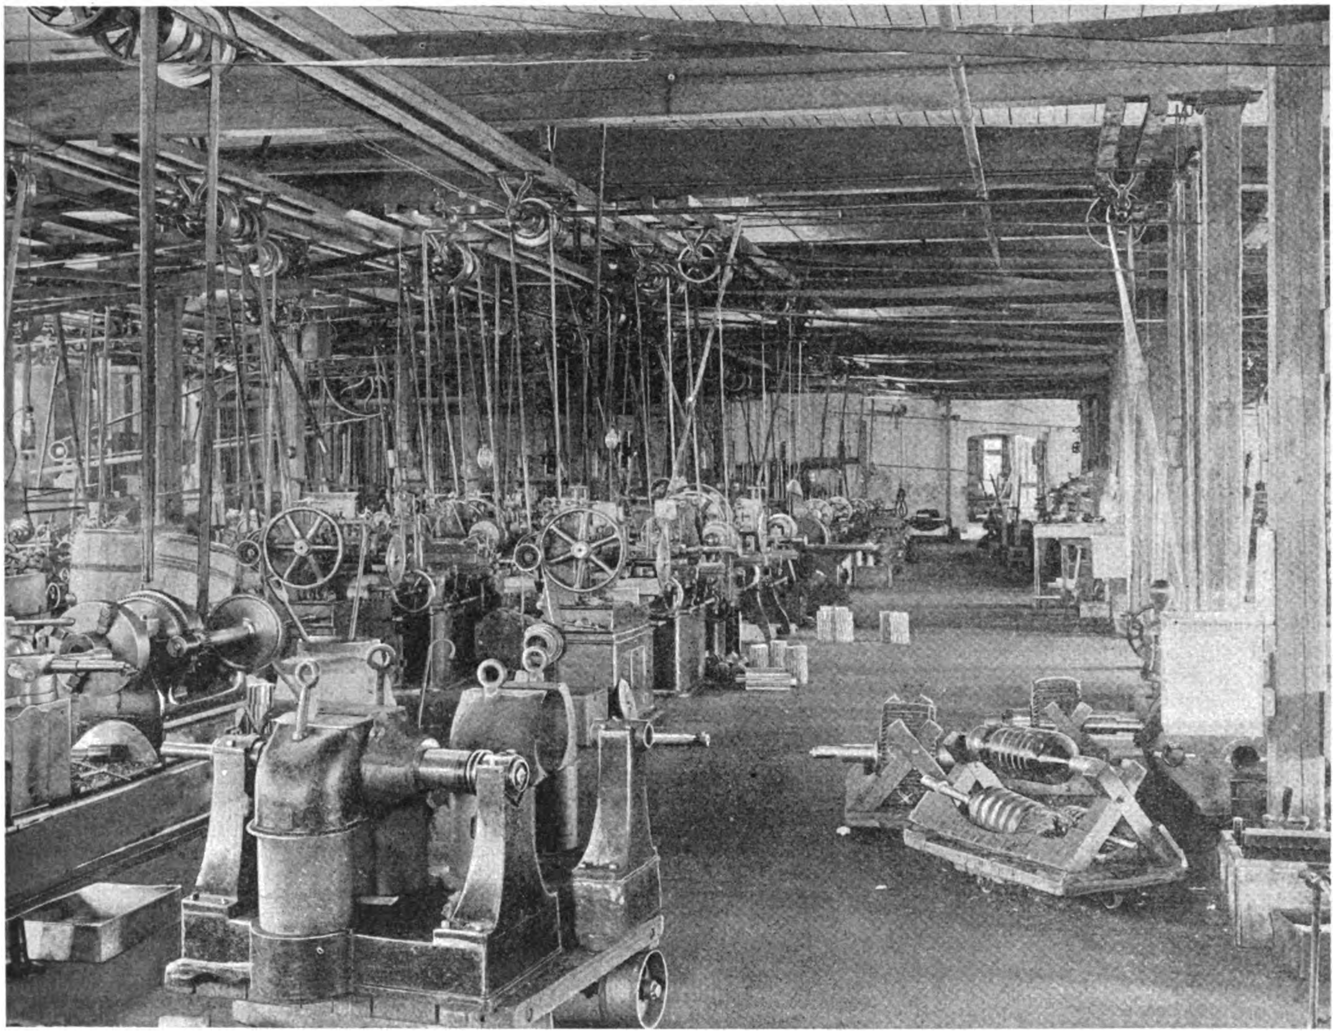
The first floor of factory J is devoted to the mining department, and here one can see electric drills, coal cutters, and various apparatus for mining work in all stages of completion. This department is kept strictly by itself, and all the necessary machinery for the manufacture of the



The Arc Lamp Testing Room.

various parts, together with the assembling, are in the one room.

Passing on we come to factory D, the second floor of which is devoted exclusively to the manufacture of the Thomson wattmeter, which has obtained so well-earned a reputation, and which is manufactured in very large numbers. The illustrations on page 654 show a few of the processes in this department, and the visitor will find in this room much that is of great interest, as the work is extremely fine and of the most exacting character. Girls are employed in this department for winding the tiny armatures, and it is curious to watch their swift moving fingers as they lightly wind the hair-like wire on the tiny cores, sort out the ends and solder them on to the commutators. The commutators are also put together on this floor, while men are busily engaged in assembling the frames, trueing the revolving copper plates, and finishing up the meter ready to be tested. This latter process is accomplished on the floor below, each meter being subjected to a time test and careful calibration before shipping.



MACHINE SHOP FOR FINISHING LIGHT WORK, FACTORY "L."

X.

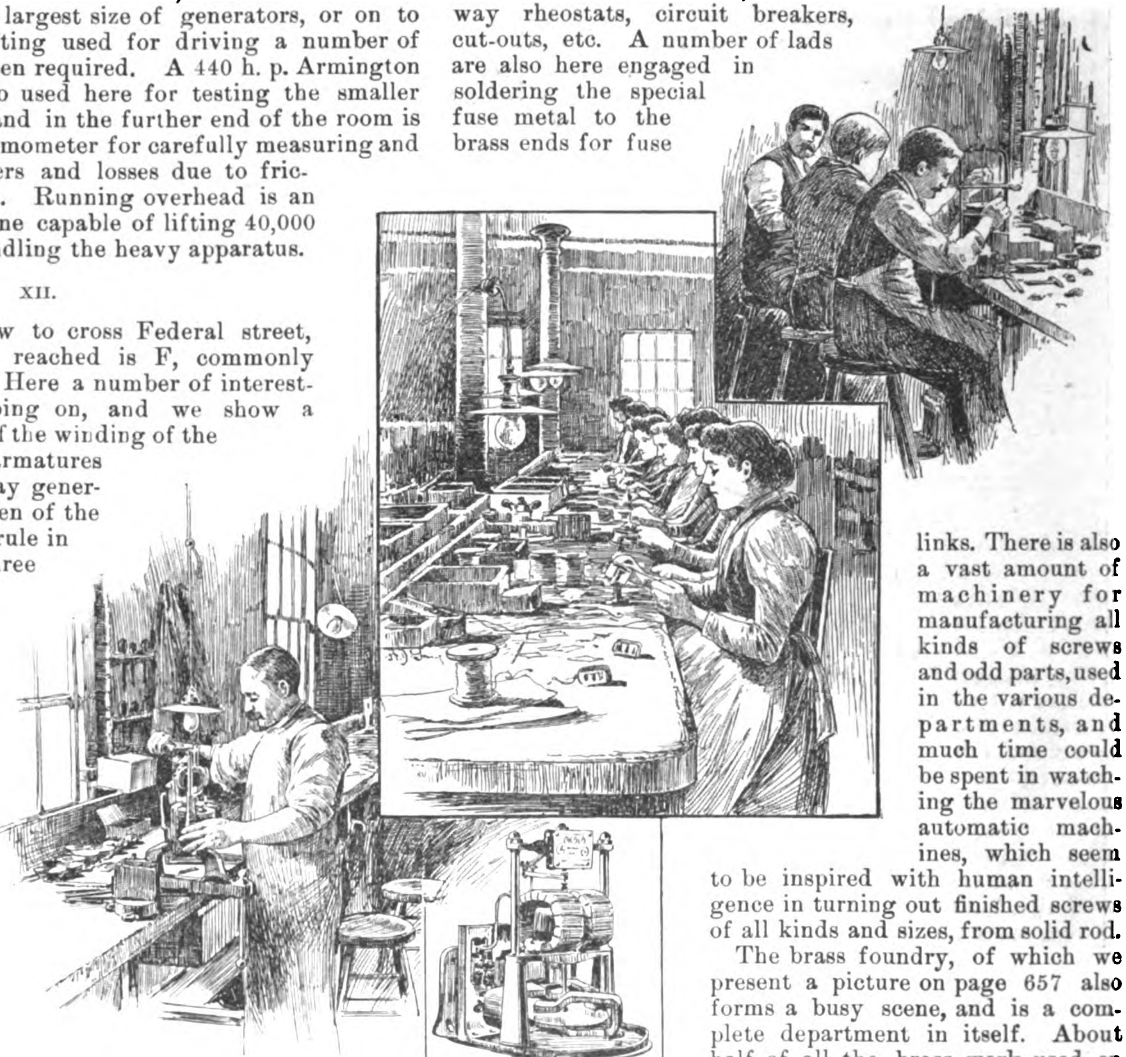
Probably one of the most interesting and attractive portions of the whole factory is the part of factory D, which is devoted entirely to the purposes of a laboratory for Prof. Thomson, into which, however, but few visitors ever gain access. This laboratory is really a genuine workshop in which are employed some half dozen skilled mechanics besides the regular assistants under the Professor's own supervision. Prof. Thomson is a skilled mechanic himself and can show a workman how to make an intricate piece of mechanism, by practically taking hold of any of the tools in the room. The room itself is fitted up with lathes, planing machines, shapers, drill presses, and all necessary tools. In the centre of the room is a switchboard from which can be derived all kinds of currents, direct and alternating and of high and low voltage. Standing round the room are models of various apparatus recently perfected, and numbers of machines and different pieces of appararatus still in the experimental stage. Attached to this room also is a complete supply department containing sheet metal of all kinds, screws, brass tubing, rods, etc., from which nearly any kind of electrical device can be made. The laboratory can be conveniently reached by a bridge from the office building and the Professor divides his time pretty equally between this room and his own private office.

XI.

Factory K, commonly called the power house is a particularly interesting one, and is devoted to the assembling a and testing of the large railway generators, and we present picture of this room, on page 655, showing an M. P. 500-volt railway generator for the West End Street Railway Company, of Boston, in the process of being tested. Ample steam capacity is provided by two Abendroth & Root boilers and four Manning boilers situated in an adjoining room, the

Fitting Thomson Wattmeters.

steam pipe connections to the engines being all carefully covered with magnesia sectional covering to prevent loss from radiation of heat. The motive power is provided by a large 750 h. p. compound Green engine, in a separate room, with the shaft extending into the power house, on which is hung a heavy driving wheel 18 feet in diameter with 67-inch face. This driving wheel has a double crown and carries two belts, so that it can drive direct onto one of the largest size of generators, or on to a line of countershafting used for driving a number of smaller generators when required. A 440 h. p. Armington & Sims engine is also used here for testing the smaller sizes of generators, and in the further end of the room is provided a large dynamometer for carefully measuring and testing the horse powers and losses due to friction and other causes. Running overhead is an electric traveling crane capable of lifting 40,000 pounds, for use in handling the heavy apparatus.



Building the Thomson Recording Wattmeter.

XII.

The visitor has now to cross Federal street, and the first factory reached is F, commonly called the car shop. Here a number of interesting processes are going on, and we show a glimpse on page 656 of the winding of the heavy Gramme ring armatures for the monster railway generators. Some half dozen of the heaviest size are as a rule in process of winding, three men being necessary for each armature, one skillful armature winder and two assistants. In another part of this shop are situated a number of heavy punch presses, shown on page 656 stamping out the laminated armature cores from the thin metal sheet. Another series of machines are busy punching out the slots in the outside circumference of these armature cores, which are destined later for the reception of the winding. The pieces for the railway rheostats are also punched in this shop, and a number of presses are also kept busy punching out large quantities of mica for various purposes. Alongside is the factory F extension which contains the forging shop, where all the smaller forgings used in the manufacture of the various classes of Thomson-Houston apparatus, are made in the usual way by the aid of a large number of steam hammers and brawny sinewed smiths. We show two views of this shop on page 657 and it will be observed that the Thomson electric welding apparatus is used extensively in this department. Passing into factory H, we come upon a busy scene, some 75 men being kept constantly employed in shipping the entire product of the various factories. In order to give some idea of the magnitude of this work it is interesting to note that during last year, 1891, no fewer than 40,000,000 pounds passed through this department, and were safely loaded on the freight cars on the adjoining tracks. Every convenience for handling this work has been provided, the railway tracks being alongside one end of the building, the tramway track which communicates with every department of the factory, running into this room, while overhead cranes, used for lifting the heavy pieces into the boxes and conveying them from one part of the room to another, are called in constant requisition. Two large stock-rooms are also situated at one end of this room, while on the floor below all the old scrap is carefully sorted out, and the different metals are assigned to different heaps for future use. The third floor of factory H is devoted to the manufacture of all kinds of small articles, such as railway rheostats, circuit breakers, cut-outs, etc. A number of lads are also here engaged in soldering the special fuse metal to the brass ends for fuse links. There is also a vast amount of machinery for manufacturing all kinds of screws and odd parts, used in the various departments, and much time could be spent in watching the marvelous automatic machines, which seem to be inspired with human intelligence in turning out finished screws of all kinds and sizes, from solid rod.

The brass foundry, of which we present a picture on page 657 also forms a busy scene, and is a complete department in itself. About half of all the brass work used on commutators, armature spiders, lamp coils, spools, brackets, etc., is here cast, a large gang of men being kept in constant employ, the remainder of the brass castings being purchased from outside foundries.

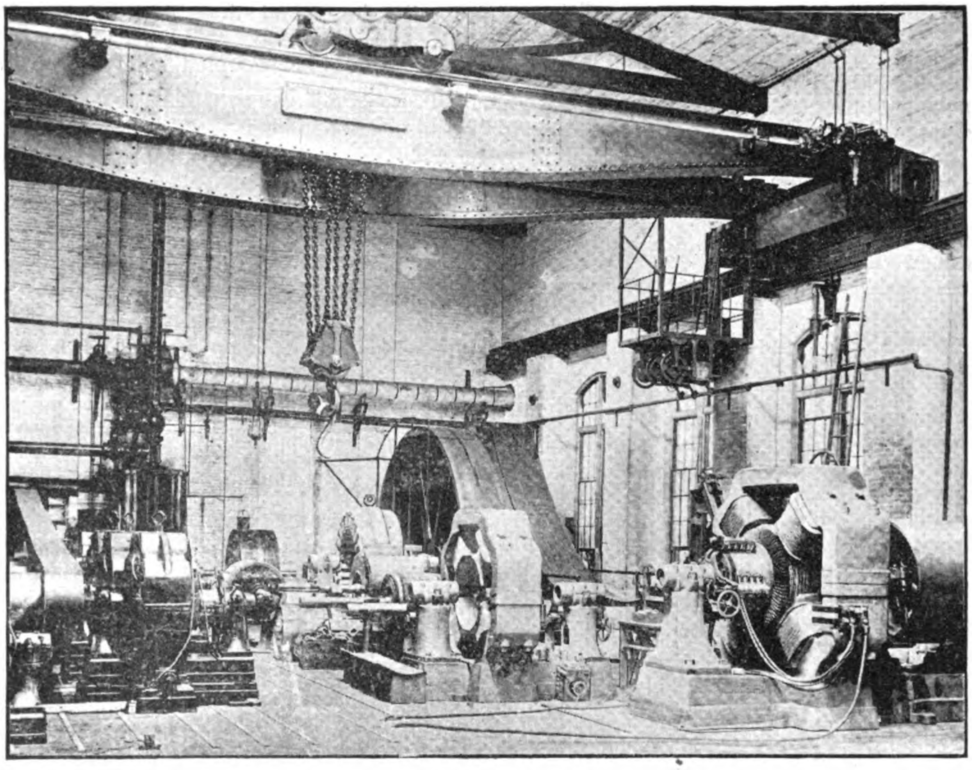
XIII.

The lighting and power circuits of such a large factory are a matter of considerable importance, and the question becomes even more involved when it is desired to use the dynamos or generators which are being tested from day to day on the shop circuits. At present there are about 300 arc lights and 3,000 incandescent lamps in daily use for lighting in the shops, and the dynamos for running them are distributed in various locations. The switchboards are interlaced in such a fashion that the load can instantly be transferred from the regular dynamos to any generator or dynamo under test. Such a combination is extremely valuable not only for testing purposes, but in the case of shutting down at night of any engine the factories can always be lit up from some other engine. Besides the lighting plant there are in use for power purposes, four 100 h. p. and one 80 h. p. generators, with about 500 h. p. of motors distributed through the shops, doing all kinds of work, such as driving shafting, elevators, cranes, electric motor cars, locomotives, etc. The system of switches is the same as for the lighting plant, so that any generator being tested can be used for this purpose.

The company are now erecting on the bank of the Saugus river, a power house, 120 feet x 250 feet, which will contain the entire electric and steam plant except that for heating the factory. As the location is about a mile from the present buildings it will be a good example of the electric transmission of power for factory use.

XV.

The rapid growth of the factory at Lynn, and the immense amount of detail work, necessarily requires a large force of clerks, draughtsmen, engineers, stenographers and other assistants, and about two years ago the handsome building known as Office Building in the plan was erected for office purposes. This building is situated on Center street, between the factories C and D, and is of convenient access from all parts of the factory. It measures 125 feet deep by 48 feet wide, and is four stories high. On entering the office building, one enters first a small reception-room, guarded by a military-looking gentleman, who requests the visitor to write his name in a large register, and will then courteously take care of his magnetizable watch while he is being shown through the factory. Behind this reception-office is situated the office of the production department, of which Mr. D. M. Barton is manager, who, with his corps of clerks, sees that the proper production of apparatus is kept up, and that a sufficient supply of new material is ordered and received.

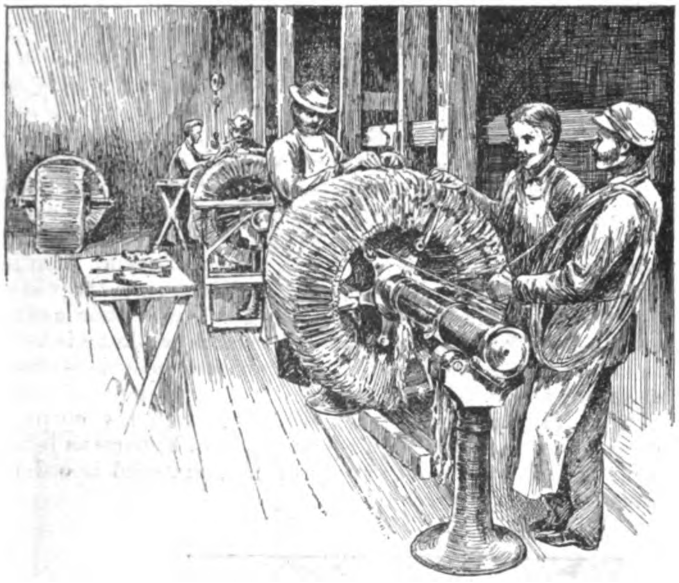


THE POWER HOUSE, FACTORY "K," SHOWING AN M. P. 500 RAILWAY GENERATOR UNDER TEST.

XIV.

A description of the factories would be incomplete without a short reference to the electric motor and tramway service which connects all parts of the different factories. There are three of these electric cars used, and they are equipped with some of the first motors here made, and have seen years of service. They are used for hauling parts of machines from one shop to the other, and can pull a trailer with several tons load up a 12 per cent. grade and around very sharp curves. Besides these there is in use in the freight yard an electric locomotive for handling the freight cars. It consists of a heavy truck equipped with two double-reduction 20 h. p. motors. It is capable of pulling a heavily loaded freight car around sharp curves and on a three per cent. grade, at the rate of about four miles an hour. The Thomson-Houston Company do all their own shifting of cars, and handle some 12 or 15 loaded cars a day, hauling them some 300 or 400 feet from the factory down to a spur track of the Boston and Maine railroad.

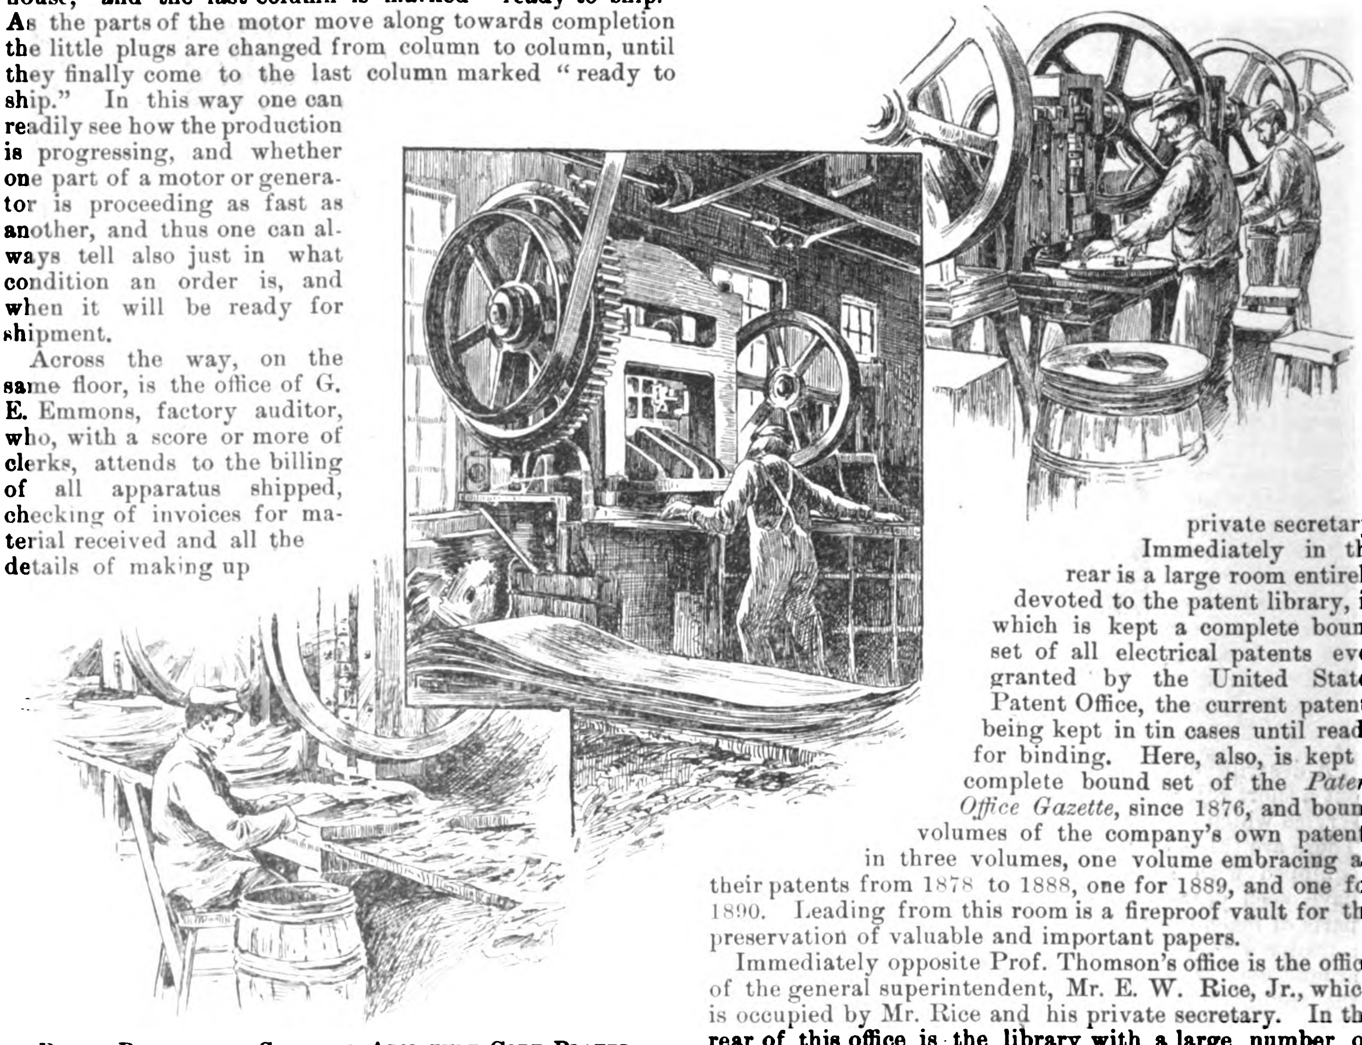
This office is fitted up with a number of boards, which are arranged as shown in the picture on page 660. They indicate to the eye the condition of every generator and motor and their principal component parts in process of manufacture. One board is provided for each of the different types built as follows: Arc dynamos, spherical type incandescent dynamos, alternating dynamos, stationary motors, motor or "D" type dynamos, railway motors, multipolar generators, special generators and motors, and all generators and motors for shop use. Each of these boards is subdivided into columns, each column having a number of small holes into which are inserted little plugs bearing the number of the part, and representing some special piece of apparatus, such as an armature, or a field or core, or, in some cases, a complete dynamo, motor or generator. Taking the railway board, for example, it is divided into columns as follows: At the left hand is a column showing the motors ordered, the class and the destination. At the right hand is a column for "fields set up," then one for "shafts inspected," another for "cores (shaft and core)" another for "winding," another for "wound," another for



Winding Large Railway Generator Armatures.

"connected," another for "baked," another for "in car house," and the last column is marked "ready to ship." As the parts of the motor move along towards completion the little plugs are changed from column to column, until they finally come to the last column marked "ready to ship." In this way one can readily see how the production is progressing, and whether one part of a motor or generator is proceeding as fast as another, and thus one can always tell also just in what condition an order is, and when it will be ready for shipment.

Across the way, on the same floor, is the office of G. E. Emmons, factory auditor, who, with a score or more of clerks, attends to the billing of all apparatus shipped, checking of invoices for material received and all the details of making up the weekly pay roll, which amounts to between forty and fifty thousand dollars.



Punch Presses for Stamping Armature Core Plates.

The basement of the office building is devoted to testing purposes, and is full of valuable apparatus. Here is situated the instrument-room for calibrating voltmeters, ammeters and various instruments for their own use in the factories. It is equipped with the highest class of instruments for accurate calibration by various methods, including a very fine Thomson quadrant electrometer, various high reading galvanometers, dynamometers, resistance boxes and all the other necessary apparatus required for delicate work.

In another part of this basement are situated a number of huge cabinets for the reception of the thousands of drawings which have been used in past years. A little further on there is a special switchboard by which any kind of current can be obtained for magnetic and other tests. Another part of the room is devoted to machines for testing tensile and compression strains of metals, and special machines for testing the torsion strains of wires and metals.

This department also contains a complete chemical laboratory for analytical work, and the company has found it to be a very valuable adjunct, as it is better able to keep up the standard of raw material which is used.

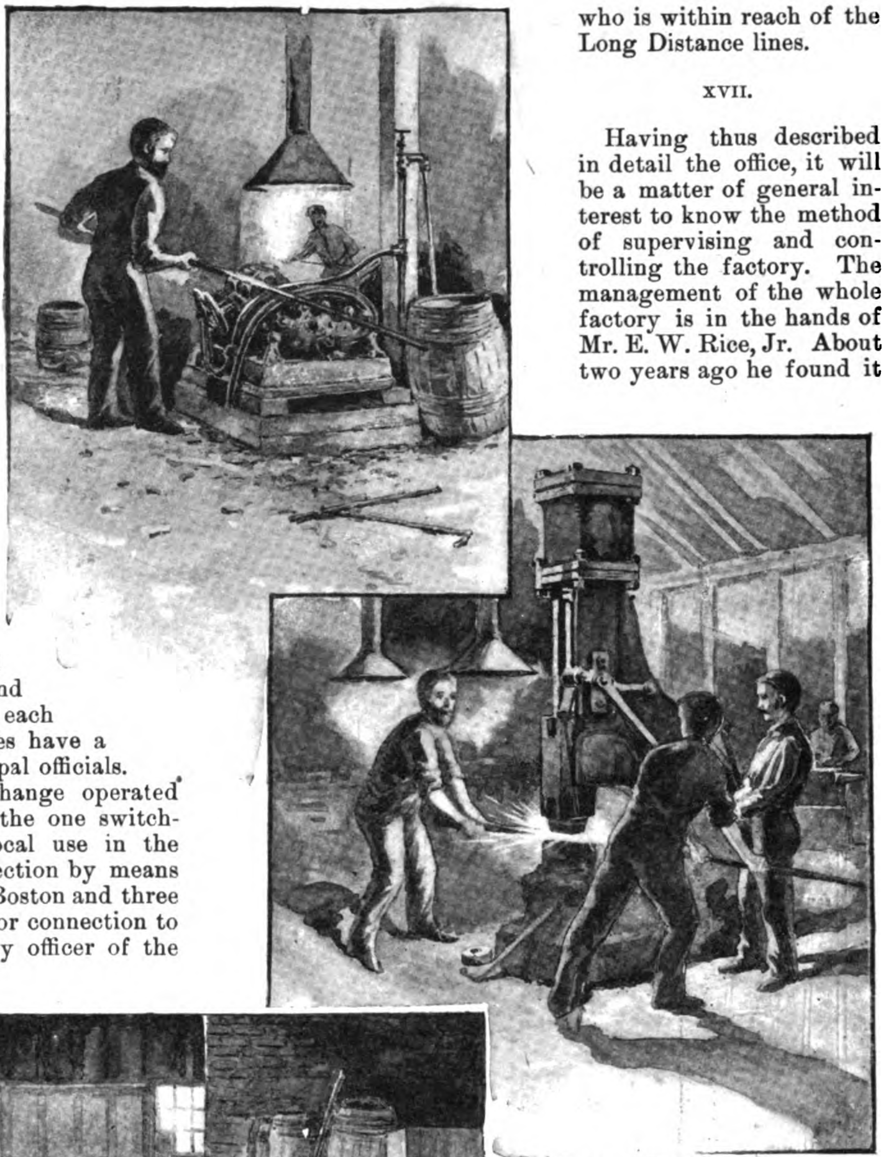
XVI.

On the second floor, occupying a front corner, is Prof. Thomson's private office, which is a bright, cheerful room, and which is occupied solely by Prof. Thomson and his private secretary. Immediately in the rear is a large room entirely devoted to the patent library, in which is kept a complete bound set of all electrical patents ever granted by the United States Patent Office, the current patents being kept in tin cases until ready for binding. Here, also, is kept a complete bound set of the *Patent Office Gazette*, since 1876, and bound volumes of the company's own patents in three volumes, one volume embracing all their patents from 1878 to 1888, one for 1889, and one for 1890. Leading from this room is a fireproof vault for the preservation of valuable and important papers.

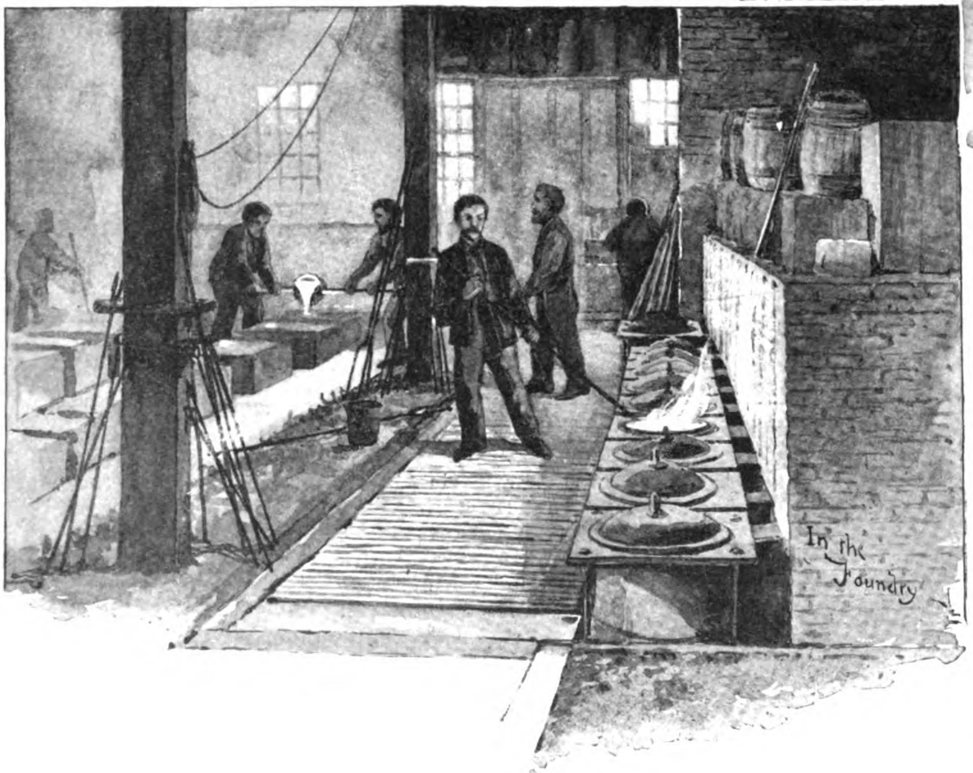
Immediately opposite Prof. Thomson's office is the office of the general superintendent, Mr. E. W. Rice, Jr., which is occupied by Mr. Rice and his private secretary. In the rear of this office is the library with a large number of books of reference and complete sets of bound volumes of the principal electrical and engineering periodicals. Adjoining the library is the office occupied by Mr. Rohrer and Mr. Knight. In the rear of the building, on this same floor, is Mr. Baker's office, who, with his assistants, looks after the mechanical details. The remaining portion of this floor is devoted to the requirements of the electrical and engineering corps, large and comfortable rooms being occupied by both departments.

The third floor is entirely devoted to the drafting-room, which is perhaps the largest and best-equipped of the kind in the country, and of which we present a picture on page 661. At present there are employed in this room alone 97 draughtsmen, engaged in designing the various devices which are manufactured in the factories. The arrangement of the drawings for ready reference is very complete. The card-catalogue system is used, and all drawings are indexed by titles and numbers both, so that any one of the 6,500 or more drawings can be referred to without any loss of time. On the roof of the building is a large and well-appointed house for the making of "blue prints," such as are well known to every engineering company; a number of men and boys are kept constantly employed at this work alone.

Each office in the building just described is equipped with one or more telephones, and there is also a telephone in the office of each foreman in the factory. These telephones have a desk attachment in the offices of the principal officials. There is also a complete telephone exchange operated by one girl, containing two switchboards, the one switchboard containing 71 drops being for local use in the office and factories, and the other for connection by means of two private lines to the head offices in Boston and three lines to the Lynn central telephone office for connection to the Long-Distance lines. In this way any officer of the company can put himself in immediate connection with any department of the factory, or can talk with any one in the Boston or New York offices, or, in fact, with any one who is within reach of the Long Distance lines.



In the Forging Shop.



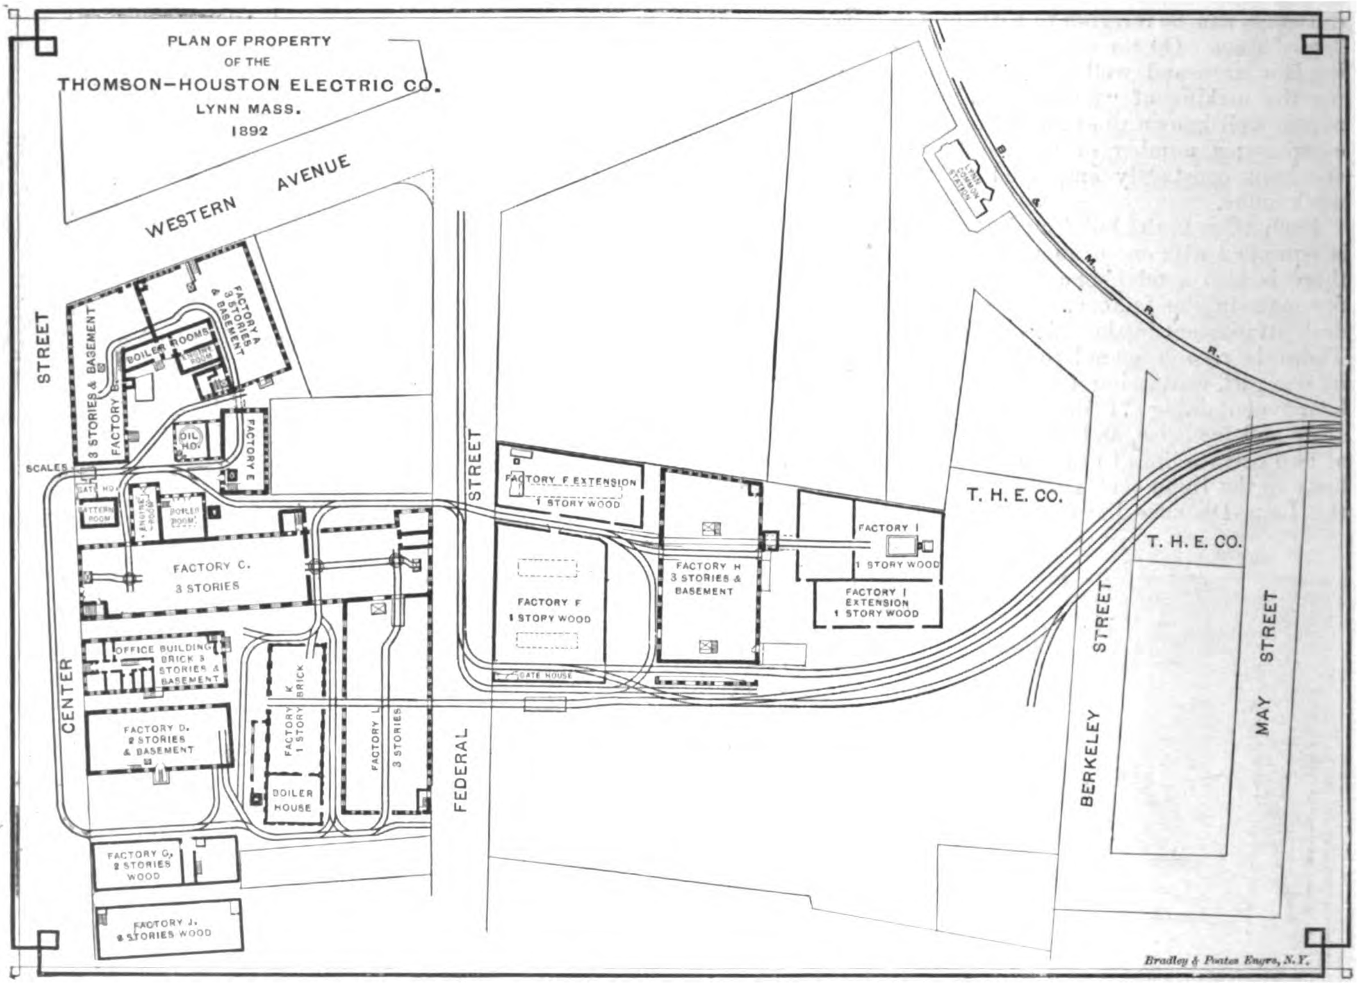
A Corner in the Brass Foundry.

XVII.

Having thus described in detail the office, it will be a matter of general interest to know the method of supervising and controlling the factory. The management of the whole factory is in the hands of Mr. E. W. Rice, Jr. About two years ago he found it desirable to adopt some means of relieving himself of a large part of the routine work in order to allow him more time to devote to the technical and engineering part of the work which is more to his taste. Accordingly the "factory committee" was organized, its purpose being to assist Mr. Rice in the general supervision of the factory and as a governing power in his absence. The committee of whom we present portraits on page 659 consists of Mr. Rice, Mr. D. M. Barton, production manager; Mr. I. F. Baker, mechanical superintendent, and Mr. G. E. Emmons, factory auditor. They hold weekly meetings, or oftener if necessary, and they deal with all problems relating to factory employees, and facilities of manufacture, and exercise a general control over the foremen.

All acknowledge that the applications of electricity have had a remarkable development in the last three years, but it is not clear to all that this has crowded the factory work in order to meet the growing and increasing demands, both in the designing of new apparatus and in the manufacture of the same. The Thomson-Houston Co. has systemized its engineering force in such a way that it has been able to meet these demands in a very satisfactory way by subdividing the work into different departments, with an experienced engineer, specially skilled in that branch, at its head. The chief of these is the railway department with Mr. W. H. Knight, as chief engineer, who devotes all his time to railway work and has an efficient corps of engineers under him to whom he delegates parts of the work.

The other chief engineers are as follows: Mr. F. O. Blackwell, mining apparatus; Mr. J. P. B. Fiske, stationary motors; Mr. Axel Ekstrom, alternating apparatus, and Mr. H. G. Reist, multipolar generators. It should be stated here also that Prof. Thomson is also called upon when any very important question arises, and Mr. Rice exercises a judicial supervision of all the departments, being ably assisted in this by Mr. A. L. Rohrer. These departments have been organized for the purpose of bringing any apparatus carefully through its experimental stage, to a state of perfection, after which they are required to keep a careful watch on the production to keep it up to the high standard of excellence, all questions regarding the working of the apparatus or complaints being referred to them for reply. In addition to the gentlemen named above, there are a number of other engineers who are able intelligently to take up any problem which may arise, who form a complete corps of electrical and mechanical engineers capable of developing any of the electrical engineering problems of the day.



Plan Showing Location and Arrangement of the Thomson-Houston Factories, Lynn, Mass.

XVIII.

A word or two by way of biography may not be out of place as to the men just mentioned as constituting the executive of the factory. First and foremost, of course, comes Prof. Elihu Thomson himself. He was born in Manchester, England, in 1853, of Scotch and English parentage. At the age of five Elihu Thomson went with his parents to Philadelphia, U. S. A., where they settled. He was educated in the public schools of Philadelphia, and graduated at the Central High School in 1870. After graduation, at seventeen, he spent six months as analyst in a laboratory in Philadelphia, and first lectured in public about this time. He was then appointed Assistant Professor of Chemistry and Physics in the Central High School in the fall of 1870, having charge of the chemical laboratory. This position he filled until promoted to the chair of Professor of Chemistry and Mechanics in the same institution in 1876. He lectured frequently on scientific topics, and had charge of the Department of Chemistry in the Artisan's Night School of Philadelphia. He was appointed lecturer on electricity at the Franklin Institute in 1877 and worked on its committees, notably the committee on dynamo-electric machines, the report of which was published in 1878. He had been at work on dynamo machines and electric lighting from 1874, and later associated with himself in such work Prof. Edwin J. Houston. Several joint patents were taken out with Prof. Houston, notably the three-coil armature and regulation of current by the shifting of the commutator brushes. Upon these and other inventions the American Electric Company, now the Thomson-Houston Electric Company, was organized in 1880, and Prof. Thomson became its electrician, resigned his professorship at the Central High School, and removed from

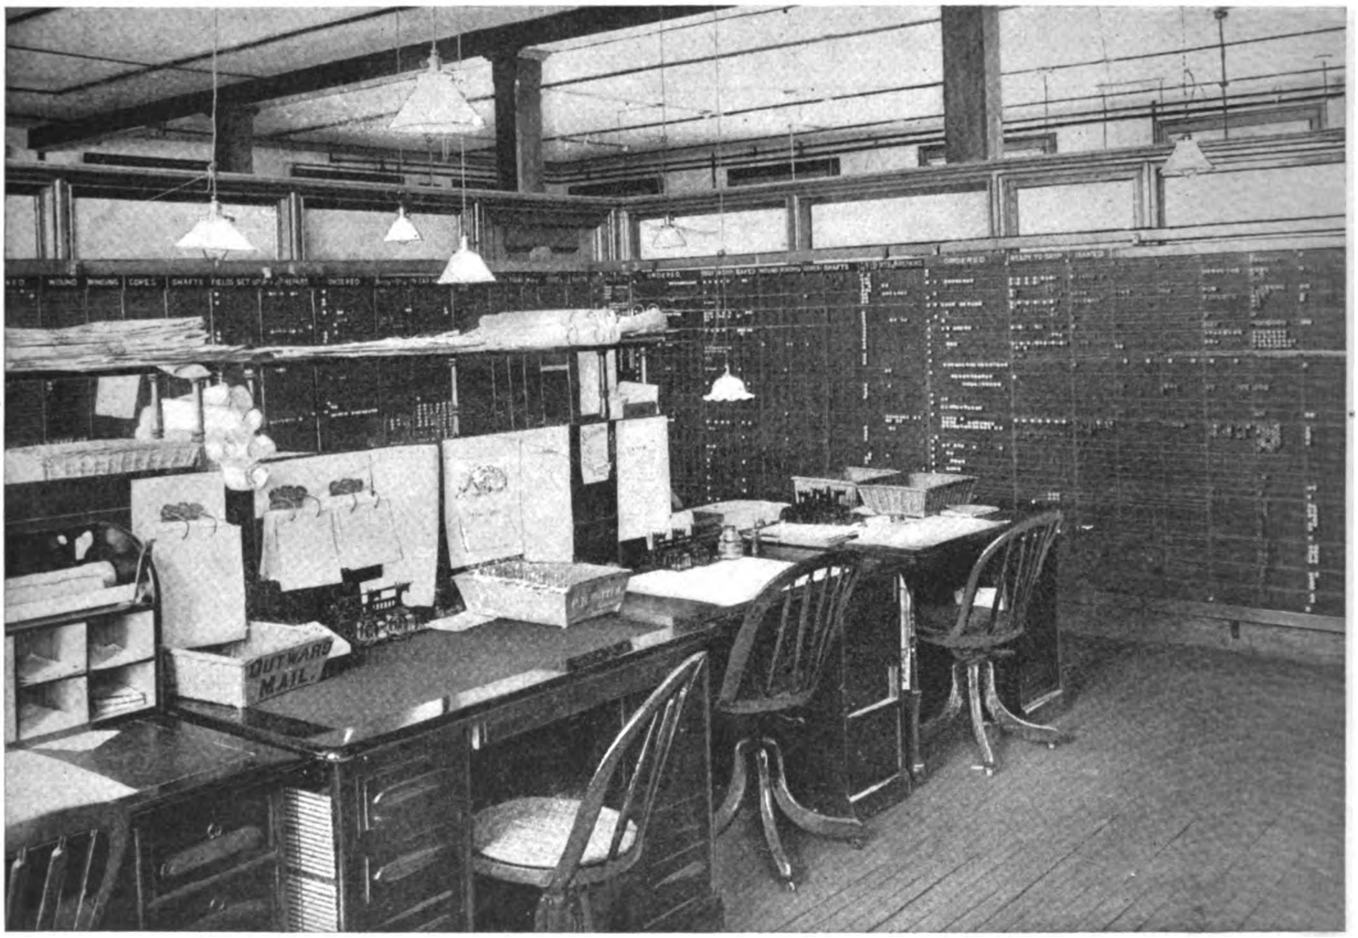
Philadelphia to New Britain, Conn., where the works were first established. Prof. Thomson's career since that time is known to everybody.

Although a very young man, E. W. Rice, Jr., occupies a distinguished position in the electrical profession. Since 1885 he has had general charge of the technical and manufacturing departments of the Thomson-Houston Electric Co. and besides has been a prolific inventor. Mr. Rice was born in La Crosse, Wis., May 6, 1862. After residing for short periods at that place, Red Wing, Minn., and Milwaukee, he removed, with his parents, to Philadelphia and graduated from the Philadelphia High School in 1880 with the degree of Bachelor of Arts, subsequently receiving the degree of Master of Arts. In 1880 Mr. Rice accepted a position with Prof. Thomson, who had formed the old American Co. at New Britain, Conn., and was engaged for some time in building instruments, experimenting and doing general work. Under Prof. Thomson's instructions he made the drawings, wound the armature, did the assembling and testing and supervised the machine work for the first machine constructed by the company—a one-light arc dynamo. The company's first plants were also installed by him. During that period Mr. Rice made many inventions which are now in use by the Thomson-Houston Company, in addition to a large number of designs and improvements, which, while not necessarily patentable, have yet been of practical value to the company. In his own name, and jointly with Prof. Thomson, he has up to the present time been granted about 50 patents, covering inventions on arc lamps and dynamos, methods of regulation, systems of distribution, incandescent dynamos, meters and general details, and he now has a large number of applications in the Patent Office.



Plug Boards in the "Production Department" Showing the Condition of the Work in Every Department.

Albert L. Rohrer was born in Montgomery county, Ohio, in 1856 and spent his early life on a farm. He received an academical education and after graduating at a normal school taught in the public schools for several years. About this time he became interested in telephonic work and did some experimental work. He then took a special course in mechanics and electricity at the Ohio State University and while at this institution he made efficiency tests on several isolated lighting plants in the city of Columbus, Ohio. He was assistant to the jury on electric lighting at the Cincinnati Exposition of 1883. In June of 1884 he became connected with the T.-H. E. Co. and has been identified with them either as expert, foreman, or engineer ever since.

Walter H. Knight, who has been identified with the electric railway industry since 1883, began his business life as a machinist at Lane & Bodley's, Cincinnati, Ohio. He then spent over six months at the Centennial Exhibition in Philadelphia reporting on machine exhibits, and then took a technical course at McMicken University in Cincinnati. He was afterwards employed as an examiner in the electrical department of the United States Patent Office, from which he resigned in 1883 to engage in the electric railway business as engineer for the Bentley-Knight Company. While working for this company he installed an experimental road at Cleveland, Ohio, and during the following year he exploited the first electric street railway in this country on the East Cleveland line. This line was operated by a conduit in connection with an overhead line, and the motors were at first run in series but afterwards in multiple, being the first instance of both methods, as it was the first road operating a plurality of motors.

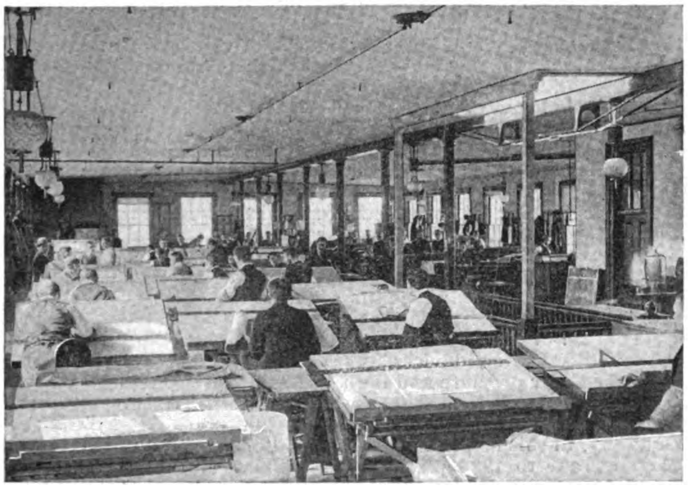
Mr. Knight's next experience was at the Rhode Island

Locomotive Works, where he constructed an experimental road at Woonsocket, R. I., and then a combined trolley and conduit road at Allegheny, Pa. Both of these roads were operated by Thomson-Houston motors and dynamos.

Determined to pursue the conduit system to a definite conclusion, a still larger installment was put in on the West End Road, in Boston, but the difficulties encountered with the severe climate and the poor quality of American street pavements rendered the service too unreliable to justify further experimentation.

The subsequent efforts of Mr. Knight were directed wholly to the overhead system. In 1889 Mr. Knight was called to London to testify before the Parliamentary Committee on the feasibility of operating underground trains by electricity, and he submitted plans showing electric locomotives with gearless motors. Upon his return to this country, the Thomson-Houston Electric Company having obtained a controlling interest in the Bentley-Knight Company, Mr. Knight entered the services of the former company, and after some time spent in the Patent Department in Boston, was placed in charge of the Railway Engineering Department at Lynn, a position which he still occupies.

Daniel M. Barton was born in Ware, Mass., in 1843. He received a common school education and was apprenticed to learn the trade of boot-maker. When only nineteen years old he enlisted for the war in the Tenth Massachusetts Regiment, and after several years' service returned home and was employed for a number of years in various mercantile firms. Part of the time he was with his brother Mr. S. A. Barton, one of the founders of the Thomson-Houston Co., in the newspaper and periodical business in Lynn, Mass. In February, 1886, he was employed by the Thomson-Houston Electric Company as a clerk and has been with them ever since. During the last three years he has been production manager at the works.



THE DRAUGHTING ROOM.

George E. Emmons was born in Westchester, Ct., in 1857. He received a common school education and at the age of fifteen began serving a six years' apprenticeship in a country general store. After this he was employed for one year by T. R. Pickering & Co., Portland, Ct., and then accepted the position as book-keeper for the American Electric Company, at New Britain, Ct. After the controling amount of stock was purchased by the Brush Company representatives, he entered the service of the firm of the North & Judd Manufacturing Co., saddlery hardware manufacturers at New Britain, Ct., and was principal book-keeper and confidential clerk for this firm until 1886, when he resigned to accept a position with the Thomson-Houston Electric Company, at Lynn, Mass., with whom he has remained ever since.

I. F. Baker, the mechanical superintendent of the factory, was born at Birmingham, England. He was at school until he reached twelve years of age, and soon after he began to learn the trade of gunsmith. He completed his technical education in the night classes at the Birmingham Midland Institute and the School of Arts. Upon coming to this country, he worked for Pratt & Whitney, the Whitney Arms Co., and the Winchester Repeating Arms Co. In 1880, he became associated with the United States Electric Co., and then entered the service of the Thomson-Houston Electric Co., in 1886.

COMING DEVELOPMENT OF ELECTRIC RAILWAYS.—III.

BY FRANK J. SPRAGUE.

Every system has its limitation. The electric is not exempt from this law, and hence I will set forth what are well-known limiting laws concerning the transmission of energy. They have been stated time and again, but people often lose sight of them in discussing the question of investments in large electric railways, so that I think it would be well perhaps to restate and emphasize them.

The weight of copper necessary to transmit a given amount of power with a fixed loss will vary inversely as the square of the electromotive force used.

The distance to which it can be transmitted with a given weight of conductor will vary directly as the pressure.

The distance to which it can be transmitted over a conductor with a given cross-section will vary directly as the pressure.

The weight of copper necessary where the supply station is in the centre of a system is only one-quarter that required if the station is at one end.

The weight of copper will vary inversely as the square of the number of supplying stations properly placed.

The electromotive force required will vary inversely as the number of stations.

Lack of knowledge of these simple and inalterable laws has led to much misconception of electrical possibilities, and these have not been confined to electrical engineers. In many of the suggestions which have been made, even by practical steam engineers, there has been an unnecessary confusion of the inpracticable and the practicable, and the specific object which should have been borne in mind has been lost sight of. Committees have drawn impossible specifications for trunk line service, and demanded of electric motors a capacity and performance superior to that of the best compound steam locomotives. I unhesitatingly pronounce any attempt to build such machines, for the present, certainly unnecessary and impracticable. The service thus suggested, if at all needed, will for many years be better performed by the steam locomotive than the electric.

Leaving out of present consideration trunk line work, there are three problems requiring solution in the application of electricity to propulsion on a large scale under conditions existing, for example, in Chicago or any other place where there is a movement of a large number of trains on more or less complicated tracks as will be found at almost all terminal railway stations. They are: First: The development of an electric locomotive of ample power which shall be as readily controlled as the steam locomotive, shall be reliable in operation, and shall show a higher economy. Of course such a machine must have all the adjuncts which are necessary for train movement.

Second: A system of conductors and methods of supporting the same which can be relied upon for ample supply of current and absolute certainty of continuous contact at all speeds on curved switches, cross-overs and the multitudinous combinations which exist on yard tracks.

Third: A system of automatic block signaling, which, while effective for steam traffic, will not be thrown out of operation by the use of tracks as conductors of electricity for a general supply. This is a more serious question than would at first appear, for this use will materially interfere with, if not absolutely destroy, the utility of what is known as the rail circuit system. This third problem is one which must necessarily follow the development of the other two, as the automatic signaling systems now existing have followed the development of steam practice. While I am not by any means thoroughly familiar with the various methods of automatic signaling, I believe I am justified in saying that there is none at present existing which will meet all the requirements of railway practice, and which can be operated on tracks used by both steam and electric locomotives, where the rail is used as a part of the supply circuit. Some of the best known systems of signaling would be rendered entirely inoperative.

As difficult as it may seem to devise such a system, I believe that it certainly can be developed, but only properly so on a section of track which is more or less experimental, on which, at the time of operation, automatic signaling is unnecessary, but which is actually operated by both classes of service. Such an experimental section would be a combination of single and double tracks with all the varieties of curves, crossings, switches and ladders; such as would be found in any large yard. It will probably be found necessary to erect a variety of kinds of conductors.

From the most careful consideration which I have been able to give to the subject, I believe there is one way, and only one way, in which the current can properly be supplied in any complicated system, and that is, from the overhead conductor, practically rigid in character, following very nearly the centre line of all tracks and switches with no movable overhead parts, and with return through the rail. The locomotive would then practically be moving between two electric planes, the lower being the guiding one.

I know there has been a great deal of talk about other possible systems of supply. We have heard much of the charged rail using low potential currents supplied at frequent intervals by motor-generators driven from a central station. Since we have discovered no conductors devoid of resistance, and the art of welding is not particularly applicable for railway service where moving contacts are a necessity, little credence need be given to any scheme of this character.

We heard again of the central rail supported on posts in wells between the tracks. A centre rail may be acceptable on a system like that of the elevated railroads, but in ordinary railroad work any ditch intended to drain a track so as to keep insulators dry and keep snow away from them would probably so open the track that any moisture and frost would cause upheavals of a serious character, and the cost of maintaining the track would be prohibitory. The use of snow machinery for keeping the track clear would be impossible, and anything underneath the car is in the most exposed place for sustaining damage by defective rolling stock and continually liable to all sorts of mechanical injuries and accidents with all the evil results of interruption of current, short-circuiting and stoppage of traffic.

Another system which has been proposed is that of a conductor supported on posts alongside of the track and elevated but three or four feet above it. While not open to so serious objections in the matter of insulation as a centre rail system, its use, where there are crossings or switches, is manifestly not to be thought of. Even on a straight, clear track in a hard climate there would be most serious trouble in the matter of clearing the tracks from snow and with the grade crossings in this country gaps in the conductors would be too great for the contacts on a single locomotive to stand.

Some time ago I was requested on behalf of a well-known financial man, whose enthusiasm as to the possibilities of electric traction is well known, but who is withal a most practical railroad man, to inspect various railroad terminal tracks in Chicago with a view of, first, the substitution of the switching work now done by a part, or all, of the 1,800 or more switch engines by electric motors, and eventually the operation of suburban service.

You have before you a map showing the railroads, nearly as they exist, on a number of systems in Chicago in the space of about two square miles, or more exactly 1¼ miles in length by ¾ of a mile in breadth; it is no exaggeration to say that there is, or will be, not less than 75 miles of track, and switches and crossings with their various combinations almost innumerable.

I went over and over some of these tracks with the one thought in my mind, How can the current be delivered to the locomotives and how can the automatic signaling be done? And I was forced to the one conclusion, to which it seems every man who makes the investigation must come, and that is, that the overhead system of supply is the only one; but that it must be as substantial and thorough in character as that of any other part of the system; and, further, that, in view of the cost, such a system is only permissible where the number of units operated is large and continuous. These conclusions are not new, but they have been emphasized by the particular problem which is here represented.

Intimately connected with the question of conductors, and one of the most serious ones which has to be met by the electrician, is that of potential. The personal danger limit, with continuous or ordinary frequency alternate currents, is pretty well determined, and it seems generally admitted by constructors that the danger limit for the continuous current machine, with its commutator, is about the same as the personal danger limit. Hence we meet with two dilemmas. If using continuous current motors, we are limited to a difference of potential per machine of 1,000 to 1,200 volts, and we can, so far as safety of the machines is concerned, only probably go above this limit by putting the motors in series, precisely as has been proposed for long distance stationary transmissions. If this is not done, then we have the introduction, between the transmitting dynamo and the receiving motor, of a motor-generator system,- another pet theory which is often suggested but which I unhesitatingly pronounce as so uneconomical as to be impracticable.

If using an alternate current system, then converters must be used, either distributed along the line and supplying the working circuit or placed upon the locomotive to safeguard the motors. While the use of a converter under these conditions is not as objectionable as the use of a motor-generator, it cannot commend itself as a very practicable scheme, and certainly in view of the fact that no single-phase simple alternate motor promises up to the present serious success.

For the present, and I think for a long time to come, we must confine ourselves to the consideration of railroad problems where continuous currents are used, and where the traffic between two points is sufficiently large to justify the investment in central stations and conductors which would be required for the operation of such assistant.

There are two methods of propelling trains electrically, one by following steam practice, that is, by building a large motor and hooking it to the head of a train, the weight of the motor being such as is required for the necessary power and traction when grades or slippery tracks are encountered. From all that has been developed up to the present to get the control that is necessary and to build the machines safely, the electric locomotive will weigh nearly as much per horse power as the steam locomotive. This weight can be better distributed, but I do not think, if steam practice is followed on trunk line service, that there could be any very material reduction of weight of train.

The other plan is to have each car propelled by one or more motors. This would be the ideal system so far as propulsion goes, provided the electric motor was unlike all other mechanical apparatus, in that it never failed, and if a number of machines could be as well taken care of, cost no more, and show as little depreciation as fewer machines of larger capacity operated as a unit.

Should we ever arrive, as we all hope, to the possession of a single-circuit alternate current motor, then, in view of the simplicity of its control, we may fairly hope for the distributed motor system. But here, also, the capacity, and likewise the weight, of the motor, being determined by the total duty done, the weight of train limit would not be decreased but rather increased.

If, on the other hand, single units are used, the query naturally arises, What form would the electric locomotive of the future take? I do not think this is by any means settled; undoubtedly gearless machines will be used, but whether they will be mounted directly upon the axle, or whether they will movably enclose the axle and be flexibly connected to it while their weight is carried on springs on the truck, or whether the motor will be carried on the truck frame and connected to the drivers by the ordinary coupling rods, are questions which will be determined eventually by the depreciation per car mile upon the motors, trucks and road-bed, as well as by the speed to be attained.

Whatever method of mounting the motor is adopted, for reasonable weights and powers, a two-axle truck will be used; but where large powers and weights are necessary, two such trucks will be coupled together so as to keep the weight upon each wheel within limits, and this will carry a cab containg the regulating and collecting devices, and so shaped as to offer the least resistance to air pressure and high speeds.

I have never advocated the use of a connecting rod in transmitting the motion from an armature to a driving axle, but I think it fair to say, in this respect, that the so-called hammering effect on the rails, said to take place in the ordinary locomotive driver where the weights are counter-balanced, exists more in imagination than in fact, and that the chief trouble in the use of the connecting rod is the change of direction of its movement.

Legal Notes.

INCANDESCENT LAMP LITIGATION.

THE UNITED STATES ELECTRIC LIGHTING COMPANY *vs.* THE EDISON LAMP COMPANY.

THE following is an abstract of the opinion of Justice Acheson, of the U. S. Circuit Court for the District of New Jersey, in the above case, which was delivered on June 21, 1892. The court says:

"This suit is brought for the infringement of Letters Patent of the United States, No. 306,980 dated October 21, 1884, granted to Edward Weston, upon an application filed May 27, 1881, for an improvement in the process of manufacturing carbon conductors for incandescent lamps. The nature of the invention is sufficiently indicated by the claim, which is as follows:

> The improvement in the art of making carbon conductors for incandescent lamps, which consists in first forming a carbon core or base, and then building up said core with carbon obtained and deposited upon the same by and during the operation of electrically heating said core, while surrounded by or saturated with a carbonaceous substance, substantially as hereinbefore set forth.

"A number of defences to the suit have been interposed; but it seems to me to be necessary to consider only two of them, namely first, the prior Letters Patent of the United States, No. 211,262 for the same invention, dated January 7, 1879, granted to William E. Sawyer and Albon Man, upon an application filed October 15, 1878; and second, the alleged public use of the invention by Sawyer and Man and those acting under them for more than two years before Weston's application for a patent.

The court then proceeded to give a summary of the testimony of Weston, and the witnesses in his behalf, which is omitted here, but will be found detailed in the opening argument of Mr. Kerr, printed in THE ELECTRICAL ENGINEER of December 16, 1891, (Vol. XII, p. 663). By this evidence it has been sought to prove that the work of Weston in this direction had preceded in date that of Sawyer and Man. After commenting upon this evidence, the court continued:

"To overthrow the prior patent of Sawyer and Man, which had issued so early as January 7, 1879, and was immediately followed by uncommon publicity, the proof of anticipation by Weston should be at least positive, unequivocal and convincing. *Cantrell v. Wallick*, 117 U. S., 689, 695; *Clark Thread Co. v. Willimantic Linen Co.*, 140 U. S., 481, 492. Taking the proofs as a whole, they fail to satisfy me that Weston's alleged invention preceded that of Sawyer and Man.

"But whatever conclusion upon the question of priority may be adopted, at any rate under the proofs, the defence of two years' prior public use of the invention before the application for the patent in suit, rests upon impregnable ground. A public use does not depend upon the number of persons to whom the use is known, and it is enough if a single specimen embodying the invention is publicly used by even one person. *Egbert v. Lippman*, 104 U. S., 333. And a public use of the invention more than two years before the application for a patent, although without the consent of the inventor, invalidates the patent. *Andrews v. Hovey*, 123 U. S., 267, 274; and 124 U. S., 694.

"In March, 1878, when Sawyer and Man made the invention here in controversy, they were engaged in completing an incandescent electric lamp of their devising, which they perfected to their satisfaction and patented in June, 1878. Between March, 1878, and May, 1879, they and their assigns made a large number of these lamps, and continuously used therein, for incandescent electric lighting, at their workshop in the city of New York, carbons prepared by the method described in and covered by their patent of January 7, 1879; and during that period they there exhibited both the actual treatment of the carbons by the patented method and the use thereof in their lamps to large numbers of persons, besides the workmen in their employ. Clearly this use of the invention, as shown by the proofs, was a public and practical use. It is here worthy of remark that the *Scientific American*, in its issue of March 8, 1879, published a clear description of the process of treating carbons as practiced by Sawyer and Man, and as set out in their patent.

"Now it may be that the Sawyer and Man lamp did not prove the success the inventors supposed it to be, and that no perfect incandescent electric lamp was produced until the fall of 1880. But still, the Sawyer and Man lamp was actually operative and had some practical utility. That it was not a commercial success is not here a controlling consideration. *The material fact is that the method invented and patented by Sawyer and Man for the treatment of carbons was put to successful practical use by them in their lamp.*

"I have only to add that it is quite evident from the proofs, that the issue of a patent to Weston was inadvertently made, in disregard of the expressed views of the examiner of interferences and the examiners-in-chief that Weston was precluded from the grant of a patent by reason of the statutory bar of two years' public use disclosed by the evidence in the interference proceedings in the Patent Office.

"For the reasons above given, and without reference to other alleged defences, the bill of complaint must be dismissed.

"Let a decree be drawn dismissing the bill, with costs."

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JUNE 14, 1892.

Accumulators:—

Secondary Battery, H. H. Lloyd, 477,182. Filed Feb. 27, 1892.

Employs an acid proof sheet provided with groups of perforations forming a network over the active material.

Alarms and Signals:—

Limiting Stop for Armatures, R. Varley, 476,845. Filed July 27, 1891.

Has for its object to lock the stop for the armatures of electric bells, etc, so that it cannot work loose.

Electric Train Signal, N. B. Cregier, 476,873. Filed Oct. 27, 1890.

Fire-Alarm System, L. G. Rowand, 477,068. Filed Dec. 14, 1891.

A thermostatic fire-alarm system.

Fire-Alarm System, L. G. Rowand, 477,069. Filed Dec. 14, 1891.

Similar to 477,068.

Fire-Alarm System, L. G. Rowand, 477,070. Filed Dec. 14, 1891.

Similar to 477,068.

Annunciator, L. G. Rowand, 477,071. Filed Dec. 14, 1891.

An annunciator for use in connection with fire-alarm systems.

Conductors, Conduits and Insulators:—

Porcelain Insulator, J. Pass and A. P. Seymour, 476,813. Filed March 21, 1892.

Consists of a porcelain shell filled with a porous cement.

Wire Cleat, A. P. Seymour, 476,827. Filed Mar. 21, 1892.

A cleat adapted to securely hold wires of different sizes.

Circuit-Breaking Insulator, A. P. Seymour, 476,828. Filed March 21, 1892.

Consists of an insulating block having grooves at its opposite ends at right angles to one another and extending along the sides to the other ends.

Insulating Tube for Electric Conductors, A. P. Seymour, 476,964. Filed March 5, 1892.

A wiring tube of insulated material held in place by lateral projections at its opposite ends.

Distribution:—

Junction Box, C. R. Arnold, 476,970. Filed March 22, 1892.

Junction box capable of being used either as a three or four way box at pleasure.

Dynamos and Motors:—

Magnetic Inductor for Dynamo-Electric Machinery, L. S. M. Pyke and E. S. Harris, 476,818. Filed Feb. 15, 1892.

Consists of laminæ of soft iron and laminæ of hard metal interspersed one with another for the purpose of strengthening the inductor.

Field Magnet for Dynamo-Electric Machines, L. S. M. Pyke and E. S. Harris, 476,819. Filed Feb. 5, 1892.

Employs a single magnetizable mass surrounding the coil on the inner and outer circumference on the one face, and extending beyond the coil on the other face.

Compensating Alternating Current Dynamo, O. B. Shallenberger, 476,830. Filed Feb. 13, 1889.

Employs a second armature, coils for establishing a field of force therefor, receiving current from the main armature, a magnetic bridge-piece between points of opposite polarity in the core of the main armature and supplemental coils wound upon the bridge-piece.

Dynamos and Motors:—

Current Alternator, H. L. Tyler, 476,843. Filed Oct. 6, 1891.

Has for its object to provide an alternating machine operated independently of current generators but used in conjunction therewith.

Electric Locomotive, T. A. Edison, 476,987. Filed Mar. 2, 1891.

Relates to supporting the motor upon the truck and means for transferring its motion to the axles.

Detachable Commutator, C. H. Gaylord, 477,175. Filed Dec. 17, 1891.

A commutator so constructed as to be readily detachable without disconnecting the wires of the armature.

Lamps and Appurtenances:—

Spark Arrester for Electric Lamps, W. M. Spencer, 476,983. Filed Feb. 5, 1892.

A screen fitting closely about the carbon of an arc lamp.

Incandescent Electric Lamp, T. A. Edison, 476,992. Filed Jan. 24, 1891.

Employs a wire connected to the middle point of the filament, and extending outside of the lamp for connection with an external circuit.

Electric Arc Lamp, T. A. Edison, 476,993. Filed Oct. 1, 1891.

A feeding and controlling mechanism for arc lamp carbons.

Electric Lamp Socket Switch, G. E. Painter, 477,146. Filed Mar. 17, 1891.

Provides means of turning the individual lamps off or on from a distance.

Measurement:—

Electric Meter, T, A. Edison, 476,990. Filed Aug. 25, 1891.

Consists of means for accurately weighing the deposited metal on the plates of electrolytic meters.

Metal-Working:—

Manufacture of Axes, E. Thomson, 476,967. Filed Jan. 22, 1889.

Claim 1 follows:

Consists in shaping the ax head in separate pieces, which are afterward electrically welded together

Electric Welding, C. L. Coffin, 477,101. Filed Nov. 6, 1889.

The method consists in resisting the passage of the current through the material in any other path than that of the proposed weld.

Miscellaneous:—

Electric Converter, G. and A. Pfannkuche, 476,816. Filed May 14, 1887.

Employs a magnetic envelope, consisting of iron particles insulated from one another surrounding the primary and secondary conductors.

Lightning Arrester, A. Wurts, 476,855. Filed Jan. 21, 1892.

Employs two bare conductors, embedded in the earth and interposed between the aerial conductor and the generator.

Pole for Electric Wires, J. Meyer, 476,889. Filed Mar. 17, 1892.

Lightning Arrester, T. A. Edison, 476,988. Filed Aug. 14, 1891.

Employs two sheets of metal foil separated by a sheet of paraffine paper and coiled in a roll.

Pyromagnetic Generator, T. A. Edison, 476,983. Filed June 13, 1887.

Employs a movable heat-directing shield operated by a motor controlled by the current from the pyromagnetic generator, which is thus made self-regulating.

Method of and Apparatus for Separating Ores, T. A. Edison, 476,991. Filed May 21, 1888.

Electric Clock Synchronizer, J. W. Dulaney and Charles F. Dulaney, 477,049. Filed Sept. 4, 1891.

Electric Elevator, J. H. Clark, 477,100. Filed June 5, 1891.

An electric controlling device for hydraulic elevators.

Railways and Appliances:—

Electric Railway, R. W. Barkley, 476,776. Filed Mar. 12, 1892.

Claim 1 follows:

In an electric railway the combination of a diving bell, an electric conductor passing therethrough, a contact-piece, an insulated conductor leading from said piece, and means for moving said piece reciprocatingly into and out of said diving bell.

Electric Railway, C. P. Tatro, 476,935. Filed July 14, 1891.

Employs an insulated conductor enclosed in a pipe and contact plungers arranged at intervals for conveying the current to the motor.

Trolley for Electric Railways, T. A. Edison, 476,985. Filed Nov. 21, 1890.

Claim 1 follows:

A current collector for electric railways having rods or spikes for making contact with the conductor and a spring pressing each rod or spike outward.

Means for Propelling Electric Cars, T. A. Edison, 476,986. Filed March 2, 1891.

A system of link belt gearing for electric cars.

Conductor for Electric Railways, T. A. Edison, 476,989. Filed August 14, 1891.

A conductor supported on pole insulators between the rails of steam or other railways; the poles rising from the bottom of drains.

Switches and Cut-Outs:—

Electric Switch, F. Broadnax, 476,781. Filed Nov. 3, 1890.

A double-pole quick-break switch.

Electric Switch, A. P. Seymour, 476,829. Filed March 21, 1892.

Employs an attached imperforate cover of insulating material serving also as the switch handle and attached to the spindle.

Telephones and Apparatus:—

Electric Switch, W. M. Goodridge, 476,792. Filed Oct. 19, 1888.

A switch adapted for use at telephone exchange stations.

Metallic Circuit House Telephone System, W. M. Goodridge, 476,793. Filed Sept. 30, 1889.

Employs a loop key having a metallic plunger provided with a groove and springs operated thereby.

Telephone Exchange Apparatus, J. A. Seely, 476,826. Filed Nov. 25, 1889.
Provides ready means of sending current over metallic circuits when they are not provided with any ground connection at the subscribers' station.

Telephone and Apparatus :—
Telephone System, B. Marinovitch & G. Szarvady, 476,887. Filed Sept. 5, 1889.
A "nickle-in-the-slot" arrangement for telephone apparatus.

A FAREWELL BANQUET TO MR. SAMUEL INSULL.

At Delmonico's this city, on Friday, June 24, a farewell banquet was given to Mr. Samuel Insull by a number of his friends on the occasion of his leaving New York to take up the duties of president of the Chicago Edison Co. Subjoined is a list of those subscribing to the banquet:

Thomas A. Edison, O. T. Crosby, C. A. Spofford, J. H. Herrick, J. C. Henderson, R. R. Bowker, John Kruesi, John Muir, T. C. Martin, S. B. Eaton, J. C. Reiff, A. Arango, John S. Wise, C. D. Shain, C. H. Coster, W. P. Hix, F. A. Stevenson, E. H. Johnson, H. Ward Leonard, C. T. Hughes, E. H. Lewis, C. L. Edgar, Thomas Butler, F. S. Hastings, W. E. Gilmore, Henry Villard, S. D. Greene, W. S. Perry, A. Marcus, J. P. Ord, G. W. Davenport, Carl Schurz, A. S. Beves, G. M. Phelps, F. R. Upton, Chas. Batchelor, C. A. Coffin, J. B. Skehan, A. E. Kennelly, Eugene Griffin, E. W. Little, J. F. Kelly, F. P. Fish, Chas. R. Lloyd, J. Hutchinson, F. Z. Maguire, R. T. McDonald, Geo. H. Roe, E. Clark, H. L. Brewster.

Nearly all the above were present. Major Sherburne Eaton officiated most gracefully as toastmaster, and speeches of unusual wit and felicity were made by Messrs J. S. Wise, S. Insull, C. A. Coffin, Eugene Griffin, John I. Beggs, E. H. Johnson, C. L. Edgar, E. Lewis, J. P. Ord. During the evening a solid silver punch bowl was presented to Mr. Insull. The occasion was interesting for many reasons, and emphasized the fact that Mr. Insull's eleven years of close association with Mr. Edison had covered a tremendous and unparalleled industrial development in the electrical field. Although very much averse to banquets and oratory—even of the best—Mr. Edison was present to do honor to one who had served him so long, so loyally and so brilliantly. Altogether the dinner was a great success, and the smoothness with which all the arrangements were carried out was due to the executive ability of Messrs. Dana Greene and Skehan.

Mr. Insull leaves New York for Chicago on June 29, and will at once enter upon his new work.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

The customer is the greatest factor in trade. You can reach him by advertising.

THE VAN NUIS "FULMEN" ARRESTER.

In the development of the Fulmen arrester, illustrated in the cut, Fig. 1, the well-trodden path in the line of indestructible designs was ignored, but the principle of a simple pair of dischargers tenaciously adhered to; because it is believed that no better path can be offered to a lightning discharge from a working circuit, than through a minimum of air gap separating a pair of dischargers connected directly to line and earth, without the interposition of magnets or mechanical contrivance. In other words, the ideal lightning arrester would be a direct connection to earth, and the nearer we approach this ideal of simplicity and effectiveness, the more likley are we to divert the atmospheric discharge into the desired channel.

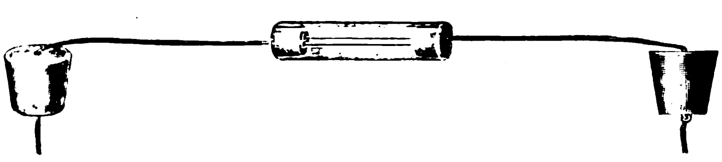


Fig. 1.—"Fulmen" Arrester.

The experience of four years of electric street railway practice, has shown that the chief difficulty in obtaining a satisfactory lightning arrester for power circuits of 500 volts potential, using a ground return, is that the dischargers are frequently destroyed by the arc which follows the lightning discharge, and this not only necessitates a new arrester but leaves that particular locality unprotected, until the new apparatus is put into position.

By utilizing the destructive agent, (the consuming arc) the Fulmen arrester is operated by the very force that continually menaces the would-be indestructible arrester.

The construction of the Fulmen arrester is simply a pair of fine brass wires, two and three-quarters inches long, made to lap each other three-quarters of an inch, with one-twentieth of an inch air gap between them. These wires form the dischargers and are held in position by a high resistance wax. A small glass tube is sealed over the dischargers, to keep them clean and dry, so that the exposed wires of the arrester, between which there is the potential of the circuit, are separated by seven-eighths of an inch of high resistance material.

The soft rubber plugs, at either end of the fuse arrester, serve to hold it in a porcelain piece, and, as shown in the cut, Fig. 2, ten fuses are attached to one corrugated cover, allowing the free ends of the fuses to project through and approach the carbon rods, forming the line and ground terminals, and located in grooves in the porcelain back.

Loose pieces of carbon, made like small wedges, connect the free ends of the upper fuse to the carbon terminals.

In this position the arrester is ready to be placed in circuit.

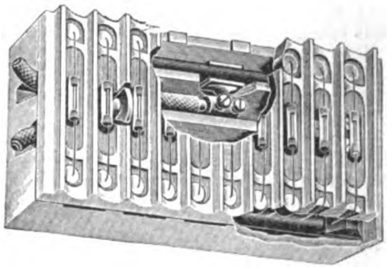

Fig. 2.—"Fulmen" Arrester.

In operation, the atmospheric discharge finds a free passage to earth, except one small gap of one-twentieth of an inch, which is promptly bridged. Once started across so small a span, the dynamo current quickly establishes a short-circuit, which completely consumes fuse No. 1, and the carbon wedges immediately drop to the free ends of fuse No. 2, bringing it into operative position.

Ten fuses are considered enough to protect one locality during a single thunder-storm, after which the arrester should be examined and any missing fuses be replaced with new ones.

The porcelain covers will be interchangeable, so that replacing fuses will amount to no more than changing covers, reloading the empty covers at leisure.

Since the operation of this arrester depends upon a short-circuit, it is designed only for circuits using a ground return or a ground wire. This arrester is made and sold by Mr. C. S. Van Nuis, 136 Liberty street, this city.

A CARD FROM MR. S. D. BREWER.

We have been requested by Mr. Brewer to publish the following open letter:

It having been brought to my attention within a day or two that printed matter is being circulated wherein my name appears as general manager of the "Hussey Re-Heater and Steam Improvement Company," I would state that I have not been connected with that company for two years.

For your further information I would advise you as follows:

In 1883 Mr. Hussey patented two re-heaters for re-heating exhaust steam. These re-heaters were manufactured and sold by Mr. Donaldson and Mr. Hussey conjointly, afterwards by Mr. Donaldson, and in 1884 by the Donaldson Heater Company, of which I was secretary. Within a few months I, individually, secured the exclusive right to manufacture and sell them.

In 1888, on the strength of certain promises, I organized with others the "Hussey Re-Heater and Steam Plant Improvement Company," of which I was general manager. But after two years with that company, I resigned as its general manager, at the same time withdrawing such interests as I had, and since then I have had no further connection with it.

I intended at the time to open an office for the continuation of my business, but while making the necessary arrangements I concluded to spend a short time in the electrical business, since I knew very little about electricity and realized that it was to play an important part in the steam business. I entered the Edison Company and only recently left it.

How long my name has been used in the manner mentioned I do not know, but I wish, even at this late day, to state that I am not interested, either directly or indirectly, in any business except my own.

Very truly yours,
S. D. Brewer,
Hussey Re-Heater System,
50 Broadway, New York.

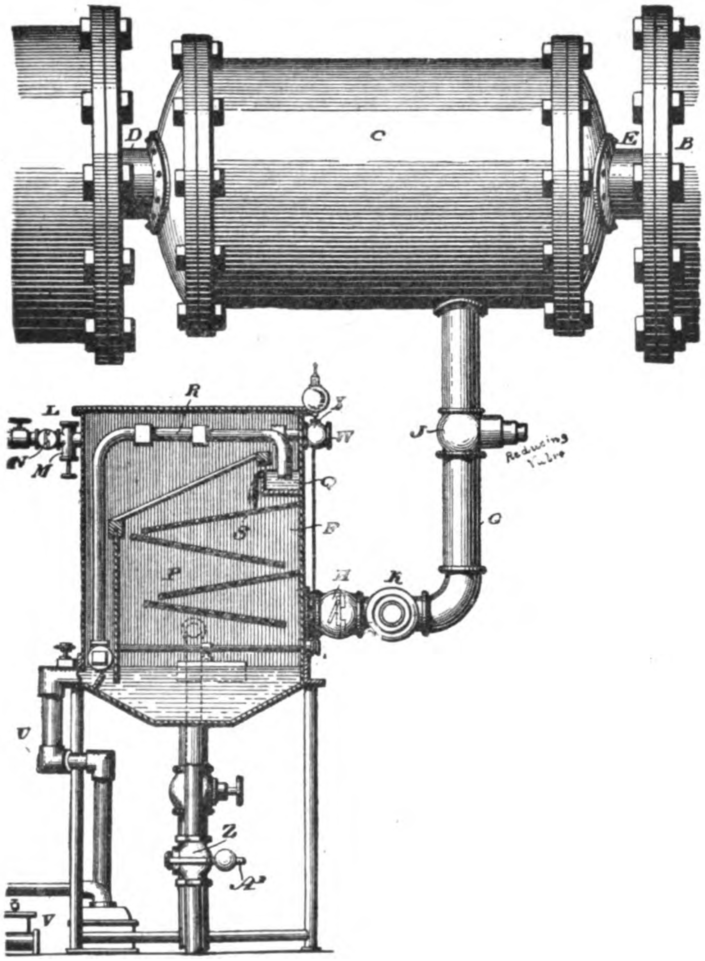
June 18, 1892.

MESSRS. WOODHOUSE & RAWSON UNITED, LIMITED.

The above firm have opened a branch office and show-room at 22 Rue Lafitte, Paris, which will be the chief depot for their French trade, where all communications should be addressed to Mr. E. Kenealy, the manager. Mr. E. H. Cadiot no longer represents the firm in France. Messrs. Woodhouse & Rawson report that they have secured another large contract, to wit, the machinery and plant for softening the water for the St. Helens Corporation Water Works. The total cost of the contract will be $50,000.

WEBSTER'S IMPROVED FEED-WATER HEATER.

It is usual in heating feed-water in connection with a compound engine to pass the exhaust-steam from the last cylinder through a coil-heater to a condenser, where, owing to the vacuum which is maintained therein, the exhaust-steam is withdrawn and reduced in pressure to such an extent that it is not practical to heat the feed-water, which is taken from a hot well at a temperature of about 100° to over 140°, when it is passed into the boiler.



Webster's Improved Feed-Water Heater.

It has been shown, however, that the best economy is attained when the feed-water enters the boiler at the boiling point, or 212° F., and in marine practice live steam under boiler pressure is, in many cases, fed directly into the feed-water heaters to accomplish this object. In order to obtain the same results without losing the work contained in the steam at boiler pressure, Mr. Warren Webster, of Philadelphia, has recently designed the feed-water heater illustrated in the accompanying engraving.

The object accomplished is to take the water from the hot well, or, if there is a coil-heater between the last cylinder and the condenser, to take the water from that at the maximum temperature which can be obtained, which would be, as previously stated, about 140°, and feed it into the water-inlet W; then to heat it to a higher temperature by steam from the steam-receiver after a portion of the energy of the steam has been utilized in one or more steam cylinders from the time it left the steam-boilers under full pressure before it entered the steam-receiver. There is taken from the steam-receiver C just the quantity of steam which is sufficient to heat the feed-water to 210° or 212.° To accomplish this the branch pipe G, is employed with a pressure-reducing valve located therein, from the steam-receiver C to the vacuum-heater, and by this the pressure in the steam-pipe leading from the reducing-valve into the vacuum-heater is cut down to as near steam at 212°, or atmospheric pressure, as possible.

By this device steam of less pressure than that carried in the steam-receiver is utilized, and the maximum amount of water is heated by the minimum amount of steam, the same being reduced by either or both of the valves J and K, as desired. The air in the heater escapes by the outlet pipe L, the check-valve N preventing its return unless the vacuum is too great, when the automatically operating inlet air valve M, which can be weighted to any desired extent, will admit the necessary or required amount.

A discharge-pipe U conveys the feed-water from the heater to a pump V.

THE NOVELTY ELECTRIC CO.'S NEW SWITCH.

Among the many new specialties being introduced by the Novelty Electric Co., of Philadelphia, none is destined to meet a more ready acceptance by the electrical fraternity than their new switch, now about ready for the market,. The full-size illustration here shown, is the size of the 5 and 10 ampere and three-way switches. Other sizes will follow in the near future. The design is very handsome. It has corrugated shell and handle, corresponding in style to the latest designs of electroliers. The shell is furnished in dipped and polished brass, plain and oxidized silver old copper, black or any finish desired to match the fixtures.

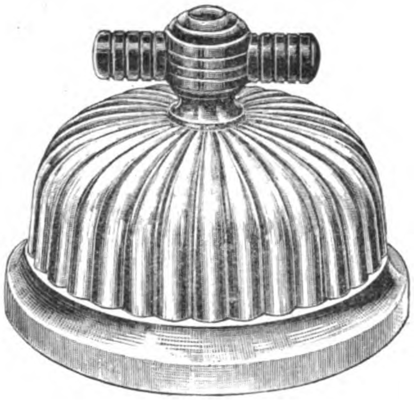


Fig. 1.—The Novelty Electric Co.'s New Switch.

The working parts of the switch are very simple in construction. The flexible contact spring is made of four leaves of phosphor bronze, insuring great flexibility and a long (nearly ⅜ of an inch) close contact, very quick double-break, breaking-in space, preventing the possibility of any metal carrying to the porcelain. The wire is quickly and easily attached, making firm close contact.

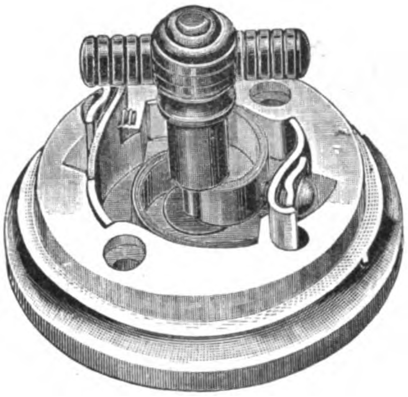

Fig. 2.—The Novelty Electric Co.'s New Switch.

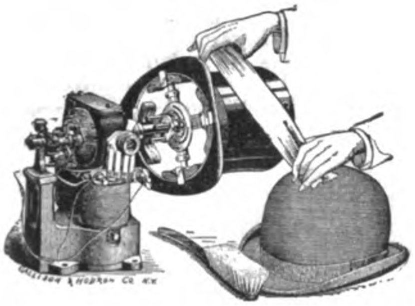
J. ELLIOTT SHAW & CO.

The countless electrical and mechanical specialties manufactured and dealt in by Messrs. J. Elliott Shaw & Co., of 632 Arch street, Philadelphia, are shown and described in their "List B" for June. This is a catalogue of 100 pages, profusely illustrated, and of convenient size. The list includes everything from books to buzzers, dynamos to door openers, galvanometers to gongs; in short, from air compressors to zinc rods, and would be interesting for the very variety, if it were not so for the quality, of its contents.

The Berlin Iron Bridge Co., of East Berlin, Conn., are now building a new machine shop for the Solvay Process Company, at Syracuse, N. Y. The building will be 50 feet wide by 300 feet long and three stories high. The side walls will be of iron and brick (combination construction), with iron floors and iron roof, covered with the Berlin Company's patent anti-condensation roofing.

The W. S. Hill Electric Company, of 54 Devonshire street, Boston, will remove its office to the Works, 133 Oliver street, the latter part of this month.

EVERY MAN HIS OWN HAT IRONER.



THE Crocker-Wheeler Electric Company are ever on the alert to find new fields in which to extend the sale of their motor. Their latest combination is in the form of a hat-polishing machine. Their $\frac{1}{16}$ h. p. or $\frac{1}{8}$ h. p. motor is fitted with a device that holds the hat firmly, so that while the shaft revolves at high speed the hat is turned with it, and the operator holds a polishing band against it, thus getting a much finer and much quicker polish than can be attained by hand.

Large numbers of these have already been used, and the time will come when every man will want to be his own hat ironer instead of heating a hat over the fire and warming himself up brushing it. He will simply turn the button, hold the brush, and the motor will do the rest.

THE RAILWAY EQUIPMENT CO.

AFTER much trying delay, the Railway Equipment Co., successor to the Electric Merchandise Co., Chicago, is ready to welcome its patrons to its elegant quarters in the Pullman Building. The rooms have been in the hands of the decorator and finisher for several weeks, and everything possible has been done to make them beautiful and comfortable. The offices front upon Michigan avenue, and are on the ground floor. To the immediate left of the entrance is what might be called the visitors' parlor—a space enclosed by a neat railing and containing table and chairs for the comfort and convenience of callers. This office fronting on Michigan avenue makes a pleasant waiting-room for visitors.

The general manager's office is also in front and just back of the visitors' parlor, and is well lighted and ventilated by one of the large avenue windows. To the rear of the general manager's office is that of the secretary and treasurer, agreeably accessible to customers. Next in order upon the right, is the book-keeping department with the necessary desks and files. Enclosed by the book-keeping department is a neat space for the use of the stenographers. The purchasing agent occupies the rear of the main office on the left, where he is conveniently near the storerooms and shipping department. A youthful usher at a desk to the right of the doorway is at your service upon entrance. The same side of the office furnishes enclosed desk-room for the salesmen, and also space for a large show board, where are exhibited all the various pieces used in electric railway construction. If one desires to see quantity, rather than to examine the quality of the company's wares, a door at the farther end of the offices admits him to a storeroom where bins and shelves filled with the many devices handled by the house line the walls. Much of the more bulky material is kept in the spacious storerooms in the basement. The rooms are well lighted by electricity throughout, and will make a delightful home for the new company.

Moving into such commodious and pleasant quarters is the natural outcome of the growth of this company's business, and a witness of its popularity with the trade. Three years ago, under another name, but with the same general manager in charge, it started in a unique business—the handling of electric railway supplies exclusively, and since then has done an ever-increasing business. Less than a year ago its quarters were found insufficient and were doubled; again it became necessary to better its facilities. A great many of the electric railways of this country are its regular customers.

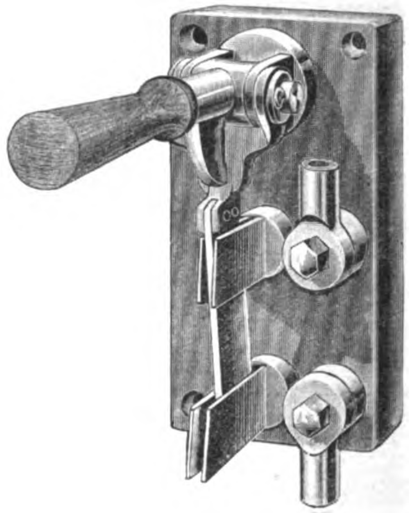
Irrespective of the pushing qualities of the company, its prosperity is undoubtedly largely due to its honest intention to furnish the best possible quality of material to purchasers. That it is imbued with a progressive spirit is evident from the frequent improvements in its devices and the continual additions thereto. All friends of the Railway Equipment Co., and of its general manager, Mr. W. R. Mason, will extend congratulations upon the appearance of its new home and its bright prospects.

A GOOD WAY TO SPEND YOUR HOLIDAYS.

THE question of the hour is, Where are you going to spend your vacation? "Don't know." Well, why not select one of the delightful spots along the Hudson, or the St. Lawrence, or among the far-famed Thousand Islands, where there is really no limit to the pleasure to be obtained, and where boating, fishing and hunting abound? These points are easily accessible, owing to the well-arranged summer plans of the New York Central and Hudson River Railroad. There is no gainsaying the fact that some of the loveliest resorts on the continent lie on or near to this great railroad system. Their complete guides, "Tourist" and other, are most desirable literature to secure just at the present time. An elaborate tourist's catalogue is being prepared, and will be ready for distribution in a very few days.

C. & C. SNAP SWITCHES.

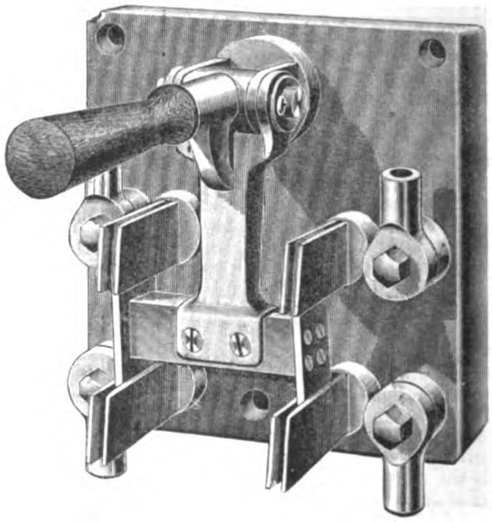
THE accompanying cuts represent the single-pole and double-pole snap switches recently placed upon the market by the C. & C. Electric Motor Co. The plain switches designed by this company have the same general appearance, the only important difference being the omission of the snap spring in the plain switch, while the handle lever and knife lever are replaced by a single casting.



C. & C. SINGLE POLE SNAP SWITCH.

Almost all specifications for electric lighting plants now call for marble or slate switchboards instead of the wood board, which was formerly considered satisfactory. The switches that were designed for the wood boards have been made to do service on the marble, but owing to their construction they do not make a handsome appearance. The switches here illustrated were designed specially for this class of work, and have been provided with ample contact surface and quick break and the metal parts are so solidly constructed as to obviate any possible danger of breaking.

The connections are made from the back of the switchboard to these switches, but the contact binding posts are made extra long so that when wanted the switches may be supplied to be fitted to a switchboard of any thickness.



C. & C. DOUBLE POLE SNAP SWITCH.

On switches provided with fuse blocks and mounted on slate bases, the distance between the fuse terminals is made ample enough to render the fuses perfectly reliable and to prevent any danger of arcing across. This feature is specially desirable when the switches are used on 500 volt circuits.

"ELECTRIC BREEZES."

MR. C. T. EVANS, of 102 Fifth avenue, Pittsburgh, Pa., has issued a very clever little bulletin under the above heading, in which the praises are sung of fan motors. He remarks that electric cold is as pleasant a theme for summer as electric heat is for winter, and that a breeze will promote energy and patience as much as a dose of quinine when one is played out or lassitudinous.

ELECTRICAL DIVIDENDS.

THE WESTERN UNION TELEGRAPH Co. has declared a regular quarterly dividend of 1¼ per cent. The surplus is now reported as being $2,098,798 for the year. The American Bell Telephone Co. has also just declared its quarterly dividend of $3 regular and $3 extra dividend, payable the middle of July. Formerly the extra dividends have been $6.

QUICK WORK BY A BULK ELECTRIC CONTRACTOR.

THE advantages which a purchaser may derive by dealing with a bulk contractor are clearly illustrated by a remarkable installation recently made at White Plains, N. Y. A very handsome new church was presented to the parish by Mrs. M. C. Reynal, and the architect, Mr. T. H. Poole, of New York City, contracted with one of the large electrical manufacturing companies to put in wiring and fixtures for electric lights, and made arrangements with the local lighting company to install a special dynamo and supply current.

It was intended to use the lighting plant at the consecration exercises, but as that day drew near it was evident that neither company would be ready. The day before the exercises the architect concluded that he must have electric lights if it were at all possible. Having had satisfactory experience with a well-known bulk electric contractor, of New York City, the architect called upon the concern at 4:30 one afternoon and asked if it would be possible to install the plant and have it running in time for the exercises, which would come of at 10:30 the next morning.

It was necessary to secure, deliver at White Plains, and install the dynamo, complete the wiring of the church, run the line to the central station plant, alter the speed of the engine, supply belting, foundation, etc.

The contract was promptly accepted by H. Ward Leonard & Co., whom Mr. Poole applied to at 4:30 in the afternoon, and at 10:15 the next morning the entire plant was operating perfectly. This is certainly a first-class argument for this method of dealing with a bulk contractor, who shoulders the whole responsibility, and whose reputation and success depend upon the promptest execution of a contract.

THE CONOVER INDEPENDENT CONDENSER.

THE accompanying illustrations, Figs. 1, 2 and 3, show the Conover independent steam engine condenser, made by the Conover Manufacturing Co., of 95 Liberty street, this city.

In Fig. 1 the condenser is seen at the right, the air pump at the left, and the engine in the middle. The air pump is vertical, and single acting, and the current of out-flowing water, mixed with the air as it comes from the condenser, is always upward.

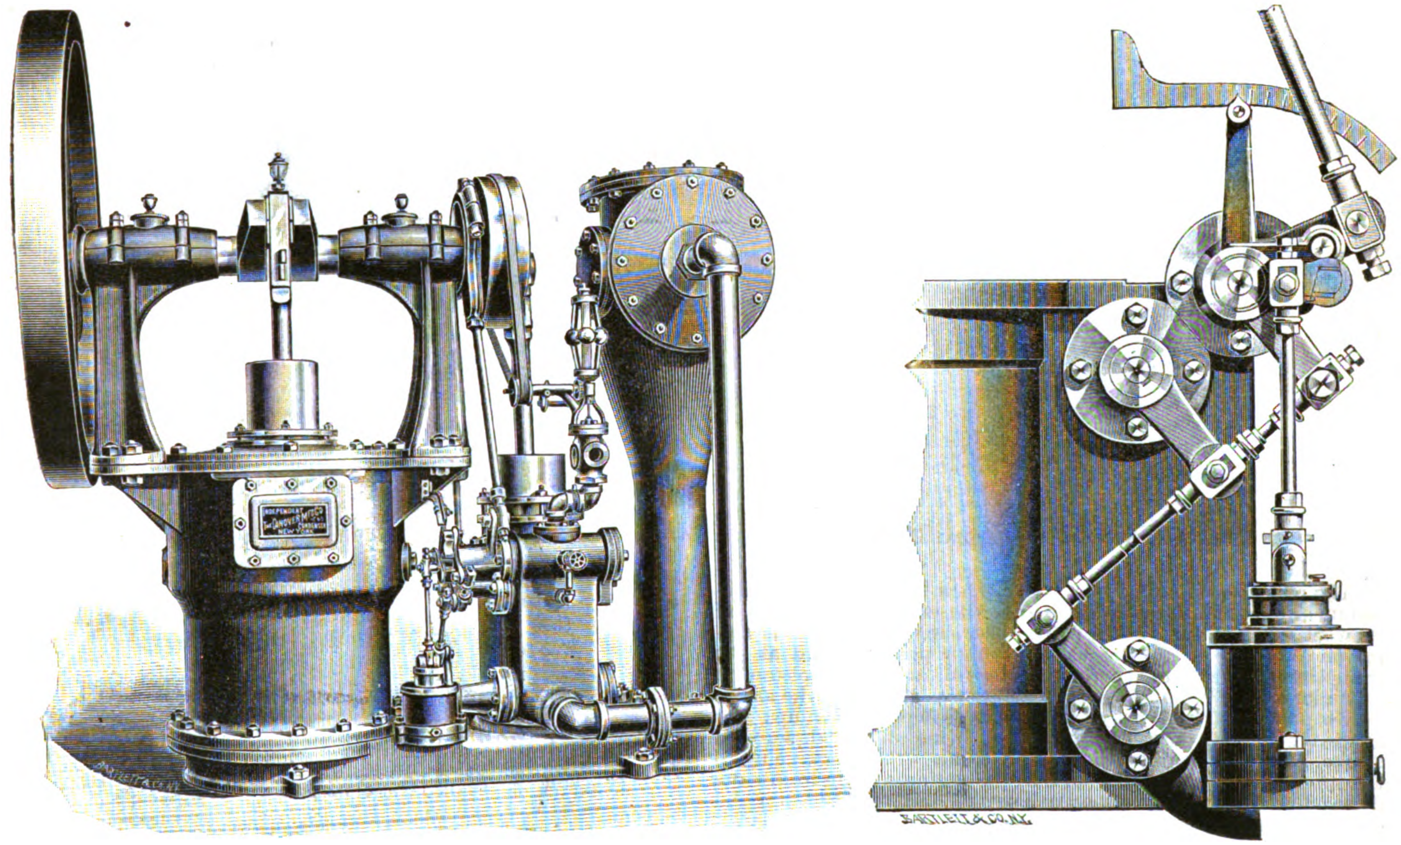
The air pump is of the trunk pattern, and being vertical and having outlets above the valves and stuffing boxes, these necessary parts are automatically sealed with water. The valves are of the best rubber and hold their seats by gravity alone.

It is claimed that this style of air pump will accomplish equal results with the horizontal, double-acting type, and with considerably less piston displacement. As it is single-acting and does all its work on the upward stroke and none at all on the downward stroke, the engine on this condenser is made to do the work on its downward stroke, called for to operate the pump when making the upward stroke.

It will be seen that when the engine is making its downward stroke it has full boiler pressure on its upward side, and the vacuum on the low pressure, or bottom, side of piston, acts on the full area of the diameter of the cylinder and in connection with the steam pressure on the top is sufficient to cause the pump to make its upward stroke.

The condenser is also claimed to run without noise. There is no foot valve at the bottom of the air pump, as the condenser at the right acts as a water column to give the proper head, and force the overflow water through the valves in the piston. On the return stroke, this water is easily forced back slightly by the condenser, avoiding all shock. Advantage is also taken of the velocity imparted to the injection water due to condensation. The pumps are made very heavy and substantial, with extra large crank pins and bearing surfaces, and are intended for continuous night and day use. The air pump is brass lined, the plunger is a solid brass casting, and the diaphragm, stuffing boxes, glands, studs, nuts, etc., are all made of brass. Over a ton of brass is used in a condenser of 1,500 h. p. capacity. In the smaller sizes the amount of brass is about one-sixth of the total weight of the machine.

The Conover special compound condensing engine is shown in section in Fig. 2. As will be readily understood, an ordinary engine coupled directly to an air pump would be compelled to store a large amount of energy in the fly-wheel, as it would be too powerful on one stroke and not sufficiently so on the other. The special engine is designed, therefore, to obviate this difficulty. It



FIGS. 1 AND 3.—CONOVER INDEPENDENT CONDENSER, ENGINE AND VALVE GEAR.

is of the trunk pattern, and the small space around the trunk on the top side of the piston forms the high pressure cylinder. Steam is admitted to the high pressure side at boiler pressure, is cut off and expanded and exhausts into the receiver, where it is admitted to the bottom side of the piston, and again cut off and expanded, and then exhausted to the condenser.

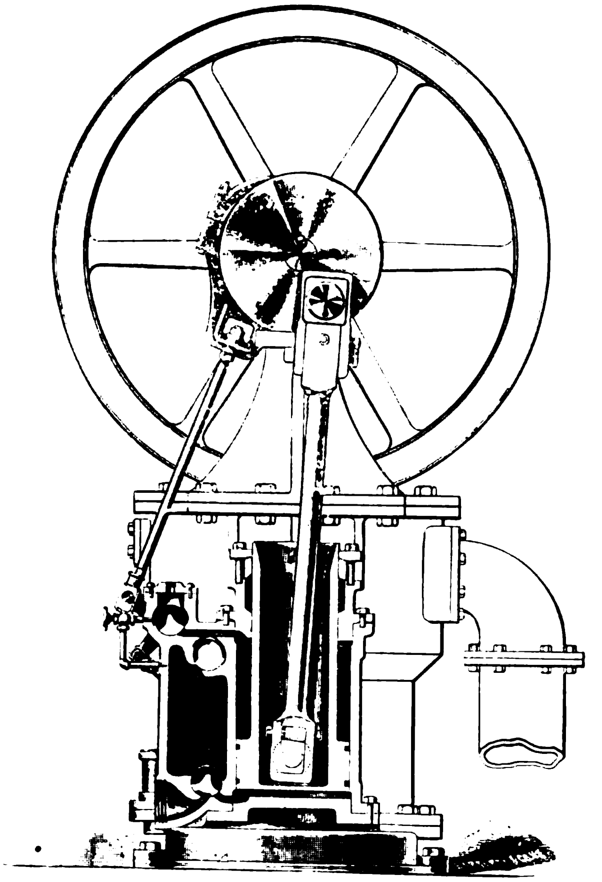


FIG. 2.—CONOVER CONDENSING ENGINE.

The piston makes the down stroke when the air pump makes the up stroke, and it will be seen that the engine does nearly all its work when making the downward stroke. The steam is acting on the upper side of the piston at high pressure, and at the same time the vacuum is acting on the full area of the piston on its under side. When the engine makes the up stroke, the steam at low pressure from the receiver acts to push the piston up; and as the air pump is doing no work then, being on its downward stroke, the engine is only called upon to keep the machine up to the speed. It will thus be seen that the engine is made to suit the demand of the large power on one stroke, and very little on the other, thus adapting itself very perfectly to the requirements.

Fig. 3 shows the arrangement of the engine valve gear. The upper end of the cylinder, on the high pressure side, has two Corliss valves. The top valve admits steam, and being fitted with releasing gear, also cuts off the steam. The point of cut-off is regulated by the hand adjustment shown. The throttle governor regulates the initial steam pressure that is required by the point of cut-off. The lower valve at the upper end of the cylinder is an exhaust valve, and has a fixed travel. The bottom valve is also a Corliss valve, and admits steam from the receiver to the bottom side of the piston. Its point of cut-off is fixed by the eccentric, and takes place at five-eighths of stroke. This valve also exhausts the steam to the condenser.

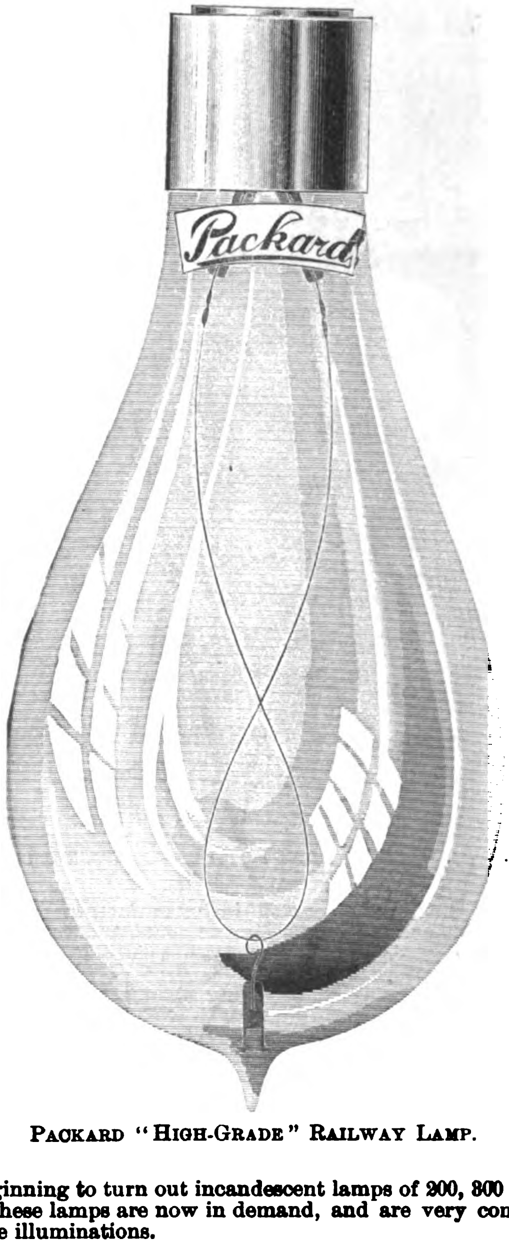
The releasing gear is a complete Corliss, and the latch plate has sixteen wearing edges. The valves are all adjustable, by means of the connecting rods fitted with right and left threads, and are also arranged to lift off their seats in case of water getting into the cylinder. The piston is made extra deep, and never exposes the upper end of the cylinder to the vacuum temperature of the lower end.

The double condenser, made by this company, has all the special features of the single machine, but the two single-acting air pumps are connected opposite one another and give a continuous and easy motion for very large powers. A special arrangement provides for connecting the central wheel to either pump, making it possible to run either side or the entire machine at pleasure. The spray in the condenser, at the end of the injection-pipe, is arranged to catch all floating matter that passes the foot valve screen. It is claimed that with this arrangement it is much easier to remove any foreign matter that collects in the spray than to allow it to go through the air pump and collect in the valves. These condensers are furnished in either belt or steam driven form.

THE PACKARD "HIGH-GRADE" LAMP.

WE illustrate through the courtesy of Mr. Chas. E. Chapin, general Eastern agent, 186 Liberty street, this city, the Packard lamps as now manufactured. The tied or supported filament lamp is used on railroads or where violent vibrations are common. It has a platinum wire cemented to the bulb and bent around the filament in the usual way.

The Packard lamps came on the market about a year and a half ago stamped "High-Grade." The general public queried "Are they?" Gradually the lamps became known, and they now merit a place among the best from the record made. They give a pure white light and are of remarkably long life. Few go things are produced by accident, and experience, appreciatio fine details, close inspection, and a thorough knowledge of business, are requisite in the manufacture of incandescent la Messrs. J. W. and W. D. Packard fill these requirements. Their company (the New York and Ohio) at Warren, Ohio are



PACKARD "HIGH-GRADE" RAILWAY LAMP.

also beginning to turn out incandescent lamps of 200, 300 and 500 c. p. These lamps are now in demand, and are very convenient for large illuminations.
